ON THE RELATIONS OF PHENOL TO PROTEINS; AND OTHER COLLOIDS. A CONTRIBUTION TO OUR KNOWLEDGE OF DISINFECTANT ACTION

BY E. ASHLEY COOPER AND EDGAR SANDERS

Introduction

The action of most disinfectants can be explained on the basis of some interaction between the disinfecting agent and the protein constituents of the organism. Formaldehyde, mercury compounds, and the halogens, all combine chemically with the proteins. Other germicides, in particular the phenols, although they cause distinctive changes in many proteins, do not appear to enter into chemical combination with them. It has long been known that phenol, like the aliphatic alcohols, behaves as a protein precipitant and the destruction of bacteria by hot water was found by Chick¹ to run parallel to the heat coagulation of the proteins. Hence the existence of a connection between the precipitation of proteins by phenol and its lethal action on bacteria was naturally inferred.

Such knowledge of these disinfectants as we possess however, dates from 1909, when Reichel² showed that phenol was absorbed reversibly from aqueous solution by the heat coagula of serum and egg-white. Later, Cooper and Woodhouse³ carried out a series of quantitative studies on the relations between proteins and phenols, of which the more general conclusions may be summarised as follows:

1. The uptake of phenol from aqueous solution by proteins first follows the partition law until a phenol concentration, fairly definite for each protein, is reached. At higher concentrations an increased phenol absorption follows accompanied by precipitation of the protein.

Albumin and globulin precipitated by other means, such as the heat coagula, also exhibit the same high solvent power for phenol.

2. A relation exists between the bactericidal power of a phenol and the concentration of it necessary to precipitate a protein. Phenols of high bactericidal power precipitate proteins at low concentrations and vice versa, but their precipitating power is not determined by their solubility in proteins alone.

Such a correspondence has been shown to exist in the case of phenol, *m*-cresol, the nitrophenols, chlorophenols, and aliphatic alcohols.

The disinfectant action of phenol thus appears to be dependent on its demulsifying action on the bacterial proteins.

The present work was undertaken to gain further information as to the nature of the change induced in proteins by the action of phenols, and to extend our knowledge of the fundamental problem concerning the mechanism of disinfection.

I. THE PRECIPITATION OF THE PROTEINS OF SERUM BY PHENOL

The albumin, pseudo-globulin, and euglobulin were prepared from serum by the usual fractionation methods with salt-solutions. The aqueous solutions of albumin and pseudo-globulin were dialysed to free from salts before use. The euglobulin was dialysed against 0.9% sodium chloride, in order to free from as much salt as possible and yet retain the protein in colloidal solution.

Each protein solution was diluted to a concentration of 0.3%.

The precipitation experiments.

The experiments were carried out in test tubes, using 1 c.c. of protein solution and 4 c.c. of phenol solution throughout. The protein solutions were adjusted to the isoelectric point, and the state of the protein was observed for varying phenol concentrations. Two blank tubes were made up with water in place of phenol. One was used as a comparison tube in detecting any slight turbidity after the addition of phenol; the other was boiled to see that the protein was readily coagulable, a condition which only obtains near the iso-electric point.

TABLE I. Serum Albumin

	Phenol Concentration	State of Protein
1.	0.08%	In solution.
2.	0.8%	"
3.	1.2%	Slight turbidity.
4.	1.4%	Precipitate on standing.
5.	1.6%	" " "
6.	1.8%	Immediate coagulation.
7.	2.0%	" "

The results show that the precipitation of serum albumin by phenol begins when the phenol concentration reaches about 1%. The filtrates from 4 and 5 gave faint positive reactions for protein. In 6 and 7 however, the protein had been completely thrown out of solution. It is therefore about as sensitive to precipitation as egg-albumin which is completely coagulated by 1.45% phenol (l. c. 1923).

The filtrates from 10 and 11 showed very faint positive reactions for protein.

The effect of phenol on pseudo-globulin thus appears to start at the very lowest concentrations—as low as 1/1000—and to increase with rising phenol concentration, until at about 2% complete precipitation takes place.

It has been shown that phenol exerts a disinfectant action at very low concentrations. Thus *Bacillus coli* are killed by a concentration of 1/500, while a concentration of 1/900 proves fatal to *Bacillus pyocyaneus*. Hence in bacteria, there presumably exist proteins capable of coagulation at these concentrations. This theory therefore receives support from the above results with pseudo-globulin.

TABLE II. Pseudo-Globulin

	Phenol Concentration	State of Protein
1.	0.08%	Gradually increasing turbidity with slight precipitation on long standing.
2.	0.2	
3.	0.24	
4.	0.32	
5.	0.4	
6.	0.8	Turbidity with precipitate separating in 1-5 hours.
7.	1.2	
8.	1.4	
9.	1.6	
10.	1.8	Coagulation, precipitate separating at once.
11.	2.0	

TABLE III. Euglobulin. (dissolved in 0.9% sodium chloride solution)

	Phenol Concentration	State of Protein
1.	0.08%	In solution.
2.	0.32%	"
*3.	0.55%	Slight turbidity.
*4.	0.84%	Precipitation on long standing.
*5.	1.15%	Precipitation in an hour.
*6.	1.25%	

* (Owing to shortage of protein, phenol solution was added to previous tubes, giving the concentration shown in Col. 1.)

The filtrate from 6 gave only a faint reaction for protein. The coagulation of euglobulin by phenol therefore begins at a concentration of about 0.5% and it is completely thrown out of solution by about 1.5% of phenol. It is more sensitive to precipitation than serum albumin. On the other hand, the phenol concentrations necessary to produce *complete* separation of protein are not greatly different:—

Egg-albumin	1.5%	(Cooper and Woodhouse.)
Serum albumin	1.8%	
Pseudo-globulin	2.0%	
Euglobulin	1.5%	

Similar results were obtained by Tebb¹ in studying the action of alcohol upon the foregoing proteins.

II. THE DISTRIBUTION OF PHENOL BETWEEN WATER AND THE SERUM PROTEINS

Measurements of the partition of phenol between water and gelatin, egg-albumin, and casein, were carried out by E. A. C. in 1912, the investigations being later extended to the chlorphenols. (l. c. 1923.)

The relative solubilities of phenol in water and the serum proteins have now been investigated to ascertain whether any relation exists between the solubility of phenol in a protein and its precipitating action thereon.

¹ Halliburton: "Biochemistry of Muscle and Nerve," p. 24.

Details of the experiments.

The method employed was similar to that described in the earlier work. A measured volume of the protein solution is introduced into a dialyser which is immersed in a known volume of phenol solution contained in a stoppered bottle. The phenol solution is estimated by Lloyd's method¹ before and after distribution and hence the solubility ratios can be determined—i.e. the ratio of the weight of phenol in 1 gram. of protein to the weight of phenol in 1 c.c. of solution in the equilibrium condition.

Subsequent dilution of the outer solution enables the reverse process—the passage of phenol from protein to water—to be followed.

The phenol, in Lloyd's method, is brominated in acid solution to give tribromphenol. Hydrochloric acid is added to the phenol solution and an excess of standard sodium hypobromite solution run in from a burette. The excess of bromine is estimated, after the addition of potassium iodide, by titration with standard sodium thiosulphate solution.

The dialysers employed in a preliminary experiment were of parchment paper, but it was found that organic matter was extracted from the parchment, giving erroneous results in the estimation of the phenol solutions. Viscose thimbles were therefore finally employed, as they caused no interference with the phenol titrations, were freely permeable to phenol, and did not absorb phenol from aqueous solution.

TABLE IV. Serum Albumin

Inside dialysers: 20 c.c. 4.09% albumin solution.

Outside dialysers: 30 c.c. phenol solution.

	Phenol Concentration		Phenol in	State of	Distribution
	Initial %	Final %	1 gm. protein	protein	ratio
1R.	0.149%	0.166	0.019	Dispersed	11.5
1.	0.296	0.248 (.248)	0.029	"	11.8
2R.	0.362	0.415	0.049	"	11.8
2.	0.749	0.637 (.637)	0.068	"	10.7
3R.	1.49	1.66	0.199	Heavy ppt.	11.9
4R.	2.07	2.32	0.28	" "	12.1
3.	2.99	2.49 (2.54)	0.306	" "	12.3
4.	4.16	3.45 (3.45)	0.434	" "	12.6

The lower phenol concentrations were analysed after seven days. With the higher concentrations, where a heavy protein clot was formed, fourteen days were allowed for equilibrium to become established. The analyses were repeated after a further twelve days, the results of the second analysis being shown in brackets in column 2. The very good agreement between the two sets of figures shows that true equilibrium had been reached.

The results marked "R" in the table were obtained by diluting the outer solution in each bottle, 20 c.c. of phenol solution being replaced by 20 c.c. of water. Two sets of equilibria were thus determined, one set while the phenol concentrations were successively raised, the other by the reverse

¹ J. Am. Chem. Soc., 27, 23 (1905).

process. The coincidence of the two sets of readings indicates that the absorption of phenol by serum albumin is a reversible process.

The high distribution ratios obtained are characteristic of a precipitated protein, similar figures having been previously found for egg-albumin after precipitation had taken place. No low distribution ratios (about 3 for egg-albumin) such as appear to characterise the emulsoid condition, have been obtained.

The constancy (within experimental error) of the distribution ratio is well marked, showing that the partition law strictly held. Phenol may thus be considered to form a true solution in the protein phase. It is remarkable that, whilst the partition-coefficient for dispersed egg-albumin is 3, in the case of dispersed serum-albumin it averages 11, although the two proteins are precipitated by phenol at about the same concentration. Evidently the precipitating action of phenol is not primarily determined by the absolute amount dissolved within the protein phase.

TABLE V. Pseudo-Globulin

Inside dialysers:	20 c.c. 2.61% globulin solution.				
Outside "	30 c.c. phenol solution.				
	Phenol Concentration		Phenol in	State of	Distribution
	Initial %	Final %	1 gm. protein	protein	ratio
1R.	0.166	0.173	0.0115	Turbidity.	6.6
1.	0.296	0.277 (277)	0.0182	"	6.6
2R.	0.414	0.426	0.045	"	10.6
2.	0.749	0.690 (.690)	0.0565	"	8.2
3R.	1.608	1.706	0.203	Ppt.	11.9
4R.	2.21	2.39	0.284	"	11.9
3.	2.99	2.68 (2.68)	0.297	"	11.1
4.	4.16	3.69 (3.69)	0.450	"	12.2

The lower phenol concentrations were analysed after seven days, the higher ones after fourteen days. The analyses were repeated after a further twelve days. The two sets of analyses, shown side by side in column 2, are identical in each case. True equilibrium had therefore been reached.

Equilibria marked "R" were obtained, as described under serum albumin, while the phenol concentrations were successively diminished. The results show that the absorption of phenol by pseudo-globulin is not a strictly reversible process. The protein, after precipitation by phenol, retained its high solvent power for that substance. More phenol was held by the globulin during descending than during ascending phenol concentrations. In this respect it resembles egg-albumin.

Even at the lowest phenol concentration employed, the protein showed signs of precipitation. Hence no distribution ratios have been outlined for the protein in the emulsoid state. The ratios of 6.6 however, probably represent the transition period where the condition of the protein is beginning to change, the ratios then rising sharply to about 12, a partition coefficient of the same value as that obtained with coagulated serum-albumin. The solubility of phenol in widely different proteins is thus of much the same order.

III. THE PRECIPITATIONS OF MUSCLE PROTEINS BY PHENOL

Of the two proteins present in meat, paramyosinogen and myosinogen, the former is characterised by the low heat coagulation temperature of 47°C . Precipitation experiments were carried out with these proteins to ascertain if any quantitative relation held between the temperature of coagulation by heat and the concentration of phenol necessary to cause complete precipitation.

Exactly the same procedure was adopted throughout as with the serum proteins.

TABLE VI. Myosinogen

	Phenol Concentration	State of Protein
1.	0.4%	In solution.
2.	0.8%	Turbidity.
3.	1.2%	Ppt. on standing.
4.	1.6%	" " "
5.	2.0%	Immediate ppt.

Qualitative tests made on the filtrates showed that precipitation was complete at a final concentration of 1.2% of phenol.

TABLE VII. Paramyosinogen

	Phenol Concentration	State of Protein
1.	0.2%	Slight opalescence.
2.	0.4%	Ppt. on standing.
3.	0.8%	Ppt.
4.	1.2%	"
5.	1.6%	"

Precipitation was complete at a final phenol concentration of 0.8%.

Paramyosinogen, which is coagulated at the lower temperature, is thus seen to be precipitated by phenol at lower concentrations than myosinogen. This relationship suggests an underlying similarity in the mechanism of the action of heat and phenol on proteins. Comparable results were obtained by Tebb (l. c.) in the case of alcohol.

IV. THE DISTRIBUTION OF PHENOL BETWEEN WATER AND EDESTIN

An examination of the behaviour of phenol with edestin was of interest, as no work had been previously carried out with a vegetable globulin. Cooper and Woodhouse (l. c.) however, had previously shown that it was precipitated from saline solution by phenol and the chlor-phenols.

Pure edestin was employed, and as the protein is quite insoluble in water, no dialysers were necessary. The equilibrium mixture was filtered from protein and the phenol estimated in a known volume of the clear filtrate.

To ensure that no protein passed the filter, a blank was employed—using $\frac{1}{2}$ gm. edestin and 30 c.c. water.

10 c.c. hypobromite soln. = 32.80 c.c. N/20 thio.

With 10 c.c. filtered = 32.65 c.c. " "

extract 0.15 c.c.

The analyses were carried out after 3 days.

TABLE VIII

	Phenol concentration		Phenol absorbed by 1 gm. edestin	Distribution ratio
	Initial %	Final %		
1.	0.200	0.183	0.010	5.6
2.	0.500	0.453	0.028	6.3
3.	1.00	0.889	0.066	7.4
4.	2.50	2.09	0.246	11.8

0.5 gm. edestin: 30 c.c. phenol solution.

Edestin thus appears to behave in a manner analogous to casein (E.A. C. I. c.), the distribution-ratio increasing with rising concentration.

This increase in distribution-ratio is not apparent in the case of the coagulated albumins and globulins, but was previously found to occur only with casein. The results may mean that the phenol molecules undergo actual *association* in edestin and casein, as is known to occur in benzene.

V. THE SOLUBILITY OF PHENOL IN GLIADIN

The class of proteins known as the prolamines or gliadins show a marked contrast in their solubility to all other proteins whether of animal or vegetable origin. Wheat gliadin, for example, dissolves in dilute alcohol of about 70% strength while it is quite insoluble in both water or absolute alcohol. It therefore seemed likely that gliadin might exhibit points of special interest in its behaviour with phenol.

A series of experiments were carried out with gliadin and phenol in different solvents:—

1. Water: protein insoluble.
2. 70% alcohol: protein soluble.
3. Absolute alcohol: protein insoluble.

It was hoped that a comparison of the solubilities of the protein for phenol in the three cases might throw some light on the change in the condition of proteins brought about by phenol precipitation.

The Distribution of Phenol between Gliadin and Water

Experiment A.

As the protein appeared to be quite insoluble in water, dialysers were dispensed with and the filtered solutions were analysed as described in the experiments with edestin. A blank experiment was performed using water in place of phenol solution. The analyses were carried out after four days.

TABLE IX

0.5 gm. gliadin : 30 c.c. phenol solution.

Blank. 10 c.c. hypobromite alone = 32.10 c.c. N/20 thiosulphate.

With 10 c.c. extract = 29.80 c.c. " "

2.30 c.c.

	Phenol concentration		Phenol absorbed by 1 gm. gliadin	Distribution ratio
	Initial %	Final %		
1R.	0.189	0.212	0.023	11.0
1.	0.441	0.379	0.037	9.9
2R.	1.027	1.217	0.161	13.2
2.	2.51	2.05	0.275	13.4
3R.	1.98	2.35	0.341	14.5
3.	4.90	3.96	0.566	14.3

The blank experiment shows that a small quantity of protein was passing the filter. To allow for this 2.3 c.c. were added to the volumes of thiosulphate solution required in the subsequent estimations.

The equilibria marked "R" were obtained by diminishing the phenol concentrations, 15 c.c. of phenol solution being replaced by 15 c.c. of water. The coincidence of the two sets of results indicates that the distribution of phenol between gliadin and water is of a reversible nature.

The distribution ratios show the high solvent power of gliadin for phenol which is of the same order as that of other precipitated proteins. The tendency for the ratio to increase with ascending phenol concentration is suggestive of molecular association, as seemed to take place in casein and cdestin.

The Distribution of Phenol between Gliadin and Water, Dilute Alcohol, and Absolute Alcohol

Three sets of equilibria were determined.

1. Phenol between gliadin and water, in which the protein is insoluble.
2. Between gliadin and 70% alcohol, in which the protein is soluble.
3. Between gliadin and absolute alcohol, which has no solvent action on the protein.

In the second of the three cases, dialysers had to be employed, as the protein was in solution. In order to obtain a strict comparison, dialysers were also employed in the other two cases. The distribution experiment with phenol between gliadin and water was therefore repeated using a viscose dialyser.

Gliadin and Water

Experiment B—with viscose dialyser.

The analyses were carried out after five days.

The results were obtained by successively diluting the outer solution in 1, i.e. all the equilibria were determined with the same portion of protein and the same dialyser.

The results are substantially the same as those obtained in Experiment A.

TABLE X

Inside dialyser : 0.5 gm. gliadin : 20 c.c. water.

Outside " 30 c.c. phenol solution.

	Phenol concentration Initial gm./100 cc.	Final gm./100 cc.	Phenol absorbed by 1 gm. gliadin gm.	Distribution ratio
I.	4.13	3.65	0.474	13.0
IR.	2.74	2.90	0.348	12.0
IRR.	2.17	2.28	0.265	11.6
IRRR.	1.707	1.801	0.190	10.5

Gliadin and Dilute Alcohol*Experiment A*—with viscose dialyser.

It was found that phenol dissolved in dilute alcohol diffused only slowly through viscose and hence the distribution of phenol between gliadin and dilute alcohol was, under these conditions, likely to take many weeks to reach equilibrium.

Experiment B—with parchment dialysers.

It seemed probable that organic matter present in parchment paper would be insoluble in alcohol, thus making it practicable to use parchment dialysers in place of viscose. Both the dialysers and the alcohol were examined as possible sources of error.

10 c.c. hypobromite solution alone = 34.2 c.c. N/20 thiosulphate.

With 10 c.c. of absolute alcohol = 33.75 c.c. " "

Br used up by alcohol = 0.45 c.c. " "

10 c.c. hypobromite solution alone = 34.20 c.c. " "

With 10 c.c. parchment extract in
70% alcohol = 33.30 c.c. " "

0.90 c.c.

The bromine used up by the alcohol and the parchment impurities together, is therefore equivalent to 0.9 c.c. of sodium thiosulphate solution. This control was neglected in the analyses, as the phenol solutions were diluted ten times before estimation.

The analyses were made after six days and again after a further four days.

TABLE XII

Inside dialyser, 0.5 gm. gliadin : 25 c.c. 70% alcohol.

Outside " 25 c.c. 6.97% phenol in 70% alcohol.

Time allowed	Initial conc. outside dialyser gm./100 cc	Final conc. outside dialyser gm./100 cc	Conc. for complete diffusion gm./100 cc
6 days.	6.97	3.61	3.49
10 days.	6.97	3.63	3.49

The phenol solutions thus diffused readily through parchment dialysers, the diffusion being complete in six days. No phenol however was taken up by gliadin from dilute alcohol solution.

Gliadin and Absolute Alcohol

Phenol dissolved in absolute alcohol diffused with extreme slowness through viscose. Hence parchment dialysers were used in these experiments.

The parchment was examined to see if soluble matter were extracted by absolute alcohol.

10 c.c. hypobromite alone	=	34.2 c.c. N/20 thiosulphate.
With 10 c.c. alcoholic extract	=	33.5 c.c. " "
		<hr/>
		0.7 c.c. " "
		<hr/>

As the phenol solutions were diluted ten times before analysis, this blank of 0.7 c.c. was neglected.

The analyses were carried out after six days and again after a further four days.

TABLE XIII

Inside dialyser, 0.5 gm. gliadin : 25 c.c. absolute alcohol.

Outside " 25 c.c. 6.99% phenol in absolute alcohol.

Time allowed	Initial conc. outside dialyser	Final conc. outside dialyser	Conc. for complete diffusion
	gm./100 cc	gm./100 cc	gm./100 cc
6 days	6.99	3.50	3.50
10 days	6.99	3.52	3.50

Hence as in the case of dilute alcohol, no phenol is taken up by the protein. The explanation is apparently that already put forward by E. A. C. (l. c.)—the high solvent power of alcohol for phenol as compared with that of the protein. The fact that viscose is permeable to aqueous, but not to alcoholic phenol solutions points furthermore to association or to complex formation in the continuous phase.

VI. THE NATURE OF THE CHANGE PRODUCED BY PHENOL IN PROTEINS

Our knowledge of the precipitating action of phenol on proteins indicates a very close relationship between the protein—precipitating action of phenol and its lethal action on bacteria. The death of the organism appears to be due to the de-emulsification of the contained protein. The greatest interest therefore centers on this change in the state of the protein which is so intimately connected with the life process of the organism.

One of us (E. A. C.) showed that a protein coagulated either by heat or phenol, exhibited the same high solvent power for phenol, an observation which pointed to an analogy between the action of phenol and the action of

heat. Pauli¹, Lepeschkin² and others have shown that analogies exist between coagulation by alcohol, phenol, and hot water. Moreover, in a recent paper, Cooper and Forstner³ have shown that those bacteria which are most susceptible to disinfection by alcohol and phenol are also most susceptible to the action of hot water.

It is known that heat coagulation occurs in two stages, first a denaturation, followed by agglutination. Thus a protein solution may be heated to 100°C. without coagulation taking place provided the solution is not at the iso-electric point. The protein undergoes denaturation in the process. Subsequent adjustment to the iso-electric point causes precipitation even though the solution be cold. Cooper and Woodhouse⁴ showed that in a precisely similar manner, protein solutions may be treated with phenol without coagulation occurring. Adjustment in reaction however, even if the phenol be first removed by dialysis causes separation of a precipitate. This observation was originally made with egg-albumin, and the present authors have now confirmed the results with purified, crystalline serum-albumin.

It is apparently the second of these stages—agglutination—which is associated with increased solvent power of the protein for phenol, the denaturation which precedes coagulation having no effect on the distribution ratios (l. c. 1923). The increase in the uptake of phenol only appeared when the protein separated out as a precipitate. Moreover, salt solutions alone—inducing a partial dehydration of the protein—did not greatly increase the distribution ratio, but subsequent movement to the iso-electric point, however, caused a sudden rise in the ratios from 7.2 to 19.8. The authors therefore concluded that the increased partition-coefficient was associated with the separation of the protein in particulate form due to the electrical adjustment of the colloidal solution.

Considered from a general point of view, the precipitation of proteins by phenol may be due to chemical action, to causes purely physical in character or to both of these, one probably consequent on the other.

If the action be chemical in nature, replacement or substitution in the amino or carboxyl groups of the protein should have a profound influence on the phenol distribution. If the action be a physical one, due to the colloidal properties of protein solutions, other colloidal solutions should exhibit analogous behaviour with phenol.

Attempts have been made to test both these hypotheses experimentally.

A. The Distribution of Phenol between Water and Gelatin Derivatives

To test the first hypothesis, a number of gelatin derivatives were prepared, all of them by attacking the amino groups of the protein.

1. Formalised gelatin in which the hydrogen of some of the amino groups is replaced by the methylene radicle.

¹ Kolloid-Z., 5, 164 (1909).

² Kolloid-Z., 32, 42 (1923).

³ Biochem. J., 18, 141 (1924).

⁴ Biochem. J., 17, 600 (1923).

2. Quinone gelatin. The action of benzoquinone on proteins probably takes place thus:—

3. Brominated gelatin.

4. Desamino gelatin. In this case some of the amino groups are actually removed and replaced by hydroxyl; in the course of the complex action of nitrous acid on protein.

The experiment with gelatin itself was repeated for comparison with the results obtained with the derivatives.

Water and Gelatin

The gelatin was washed for two days in running tap-water, followed by several changes of distilled water. Water-soluble impurities were thus removed. After air-drying, the sheets were cut into narrow strips and dried in the steam oven.

The gelatin being quite insoluble in cold water, no dialysers were necessary, the phenol solutions being removed and analysed without filtration.

A control experiment was performed, using water in place of phenol solution to ensure that no protein material passed into solution.

TABLE XIV

2 gm. gelatin : 60 c.c. phenol solution.

Blank 10 c.c. hypobromite alone = 31.30 c.c. N/20 thiosulphate.

With 10 c.c. gelatin extract = 31.30 c.c. " "

0.00 c.c. " "

	Phenol concentration		Phenol absorbed by 1 gm. gelatin gm.	State of protein	Distrib. ratio
	Initial gm./100 cc	Final gm./100 cc			
1.	0.222	0.207	0.0045	unprecipitated	2.2
2.	0.500	0.468	0.0096	"	2.1
3.	1.000	0.931	0.0207	"	2.2
4.	2.500	2.31	0.056	"	2.4
5.	4.95	3.49	0.436	precipitated	12.5

The control experiment shows that no interfering material was extracted from the gelatin.

The results are in good agreement with the original figures obtained in a similar manner by E. A. C.

Water and Formalised Gelatin

10 gm. of the washed gelatin were treated with 600 c.c. of 40% formaldehyde for three days. The product was washed in successive changes of distilled water, until no more formalin could be detected in the washings, and was then dried at 100°C. The material was quite insoluble in water even on boiling.

A control experiment was performed substituting water for the phenol solution in order to detect any errors due either to soluble protein material or traces of formaldehyde.

The analyses were made after two days and in two cases again after a further four days, the result for the two analyses being shown side by side in column 2.

TABLE XV

2 gm. formalised gelatin : 60 c.c. phenol solution.

Blank 10 c.c. hypobromite alone = 30.80 c.c. N/20 thiosulphate.

With 10 c.c. extract = 30.80 c.c. " "
0.00 c.c. " "

	Phenol concentration		Phenol absorbed by	Distribution ratio
	Initial gm./100 cc	Final gm./100 cc	1 gm. formalised gelatin gm.	
1.	0.222	0.200	.0066	3.3
2.	0.533	0.488 (.488)	.0135	2.8
3R.	0.447	0.500	.0155	3.1
3.	1.000	0.895	.0315	3.5
4R.	1.060	1.195	.071	5.8
4.	2.500	2.140 (2.12)	.109	5.1
5.	4.95	3.59	.405	11.3

The agreement between the analyses made after two days and after six days, shows that equilibrium had been reached in forty-eight hours.

The equilibria marked "R" were obtained by dilution of the phenol solutions. Their coincidence with the results obtained while the strength of the phenol solutions was being successively raised, indicates the reversible nature of the distribution.

The values for the distribution ratios are not very different from those obtained with gelatin itself. The low partition coefficient of 2 in the case of gelatin is exchanged for one of 4 (average) with the methylene derivative, which also exhibits the sudden rise in solvent power for phenol at higher phenol concentrations. No visible change however in the bulk of the protein accompanied this increase in solvent-power. Two strips only were precipitated as white sticky masses in exactly the same way as happens with gelatin. Notwithstanding, the distribution ratio, (11.3), is nearly as high as with gelatin (12.5) where all the protein is precipitated. Hence it appears that the change in the protein derivative which is responsible for the increased uptake of phenol need not necessarily manifest itself in a visible precipitation. With proteins themselves increased phenol absorption has always been accompanied by precipitation.

Water and Quinone-Gelatin

About 10 gm. of washed gelatin were treated for four days with a 1% solution of benzoquinone in water, washed thoroughly and dried at 90°C.

The product, resembling gelatin but deep ruby-red in colour, was completely insoluble in boiling water.

A blank experiment was carried out, replacing phenol solution by water, so that allowance might be made for any errors due to extraction of soluble matter from the protein derivative.

The phenol solutions were analysed after three days and again in two cases, at the end of a further four days, the results for the second analysis being shown bracketed in column 2.

TABLE XVI

1 gm. quinone-gelatin : 30 c.c. phenol solution.

Blank 10 c.c. hypobromite alone = 32.20 c.c. N/20 thiosulphate.

With 10 c.c. extract = 31.60 c.c. " "

0.60 c.c. " "

	Phenol concentration		Phenol absorbed by 1 gm. Quinone-gelatin	Distribution ratio
	Initial	Final		
	gm./100 cc	gm./100 cc	gm.	
1R.	0.129	0.134	.0072	5.4
1.	0.222	0.193	.0087	4.5
2.	0.443	0.393 (.389)	.015	3.8
3R.	0.591	0.621	.025	4.0
3.	1.000	0.886	.034	3.9
5RRR.	1.53	1.82	.067	3.7
4.	2.50	2.12 (2.13)	.116	5.5
5RR.	1.87	2.29	.156	6.8
5R.	2.29	2.80	.283	10.1
5.	4.88	3.43	.436	12.7

The control experiment shows that a small quantity of soluble matter was extracted from the gelatin derivative. To correct the error thus introduced, 0.6 c.c. was added to the volumes of thiosulphate solution required in the subsequent phenol titrations.

The agreement between the analyses made after three and after seven days shows that no further absorption of phenol had taken place. The distribution had reached equilibrium in three days.

The absorption was completely reversible, the equilibria obtained during descending phenol concentrations (marked "R") coinciding with those obtained during ascending concentrations of phenol. In fact, with the same portion of protein derivative a ratio of 12.7 was successively reduced to 10.1, 6.8 and 3.7 by diluting the phenol solution three times.

As with formalised gelatin, the partition coefficients for low phenol concentrations are greater than with gelatin. The coefficient of 2 in the case of gelatin became 4 with formalised gelatin and is raised to 4.5 (mean) with the quinone derivative.

The quinone-gelatin, although it showed no visible change throughout, yet exhibits the usual sharp rise in solvent power for phenol at higher concentrations. Hence the action of quinone or formaldehyde on gelatin, although it masks any visible precipitation due to the subsequent phenol action, does not prevent the change which is responsible for increased phenol up-take.

Water and Brominated Gelatin

10 gm. of the washed gelatin were treated for four days with saturated bromine water at room temperature. The product was washed in successive changes of distilled water, until no bromine could be detected in the washings. After air-drying the brominated gelatin was placed in the vacuum desiccator for two days.

The material was insoluble in hot water, but it gradually dissolved on prolonged boiling.

The analyses were carried out after two days and repeated in one case after a further four days.

The usual blank experiment was made with water in place of phenol solution.

TABLE XVII

1 gm. brominated gelatin : 30 c.c. phenol solution.

5.	4.90	3.43	0.441	"	12.9
6.	6.86	4.47	0.717	"	16.0

The partition coefficients for low phenol concentrations are again higher than with gelatin itself, but slightly lower than those obtained with the formalin derivative.

Water and Desamino Gelatin

The production of the desamino derivative by the action of nitrous acid on gelatin was complicated by the fact that gelatin is soluble in acids. For the purposes of the distribution experiment, it was essential to use the derivative in a form similar to that of gelatin itself, in order that the results should be strictly comparable. In the final method used acetic acid and a slight excess of sodium nitrite were employed. After careful washing, the product was dried first in the air, then in the steam oven for ten hours. Any nitrogen gas still retained within the gelatin was then driven off. The dry product was yellow, but uniform in appearance.

Analyses of the phenol solutions were made after four and after eight days and the usual blank experiment was carried out.

TABLE XVIII

1 gm. desamino gelatin : 30 c.c. water.

Blank 10 c.c. hypobromite alone = 30.7 c.c. N/20 thiosulphate.

With 10 c.c. extract = 30.4 c.c. " "

0.3 c.c. " "

	Phenol concentration		Phenol in 1 gm. desaminogel.	State of protein	Distribution ratio
	Initial gm./100 cc	Final gm./100 cc

1.	0.490	0.456	0.0102	"	2.2
2.	0.984	0.909	0.0225	"	2.5
3R.	1.42	1.60	0.044	"	2.7
3.	2.46	2.14	0.097	ppt.	4.5
4.	4.90	3.37	0.458	"	13.6
5R.	2.89	3.60	0.552	"	15.4
5.	6.88	4.33	0.765	"	17.7

In this case the low partition coefficients of 2, characteristic of gelatin itself, have been obtained. It is noteworthy that this is the only derivative in which the molecular weight of the gelatin has not been raised, the amino group being replaced by hydroxyl. The quinone derivative, in which the largest addition was made to the gelatin molecule, showed the largest increase in the partition coefficients for low phenol concentrations.

The results as a whole are of interest, inasmuch as they show that the substitution of the methylene group, the quinone nucleus, and bromine into the amino-groups of gelatin increases the solubility of phenol in the protein, yet treatment with nitrous acid has no effect on the partition coefficient.

B. The Behaviour of Phenol with other Colloids

(1) SUSPENSOID COLLOIDS.

Phenol and ferric hydroxide sol.

A solution of "dialysed iron" was used and experiments were carried out in both the sol condition and with the coagulum produced by a trace of salt.

The results showed that the colloid did not absorb phenol.

Phenol and silver sol.

A concentrated silver sol was prepared by Carey Lea's method.

TABLE XIX

5.	"	5.20	5.19	—	—

The fact that the quantity of phenol taken by the silver is identical in 2 and 3 suggests chemical action, for it is independent of the phenol concentration.

It appears from the figures for the precipitated sols that any phenol taken up in the sol condition is liberated when the sol is precipitated, the phenol concentrations returning to their original values. Thus:—

	2	3
Initial conc.	3.72%	5.20%
With Ag sol	3.67%	5.15%
With pptd. sol	3.75%	5.19%

The results with both iron and silver sols indicate that little, if any, phenol is absorbed by suspensoid colloids from aqueous solution.

(2) EMULSOID COLLOIDS.

As the proteins themselves belong to the class of emulsoid colloids, it appeared probable that an investigation of the behaviour of other members of that group with phenol might be of value. For this purpose silicic acid and soaps appeared particularly well suited; for, while they closely resemble proteins from the colloid stand-point, chemically they are very different. A similar behaviour exhibited between phenol and silicic acid or soap as between phenol and protein would therefore very strongly suggest a physical interpretation of the foregoing observations.

Water and silicic acid.

Experiments showed that silicic acid did not absorb phenol from aqueous solution.

Water and sodium stearate.

As sodium stearate is practically insoluble in cold water, dialysers were not at first used, the solutions being merely filtered before analysis. With rising phenol concentration however, the soap gradually dissolved, and on acidification in the course of the phenol analyses a precipitate of fatty acid appeared and this underwent bromination, causing serious errors in the analyses. Viscose dialysers were therefore subsequently employed.

The analyses were made after five days and repeated in two cases after a further fourteen days. A blank experiment was carried out.

* (20 c.c. phenol solution outside dialyser.)

The soap dissolved gradually in the phenol solutions as the concentration of the latter rose. The solution outside the dialysers however were in every case free from soap, as judged by the absence of precipitate on acidifying. With the higher phenol concentrations a considerable quantity of water passed into the dialysers from outside.

The equilibria marked "R" were obtained during falling phenol concentrations, 10 c.c. of phenol solution being replaced by 10 c.c. of water. The results indicate that the absorption was reversible to some extent, but the figures are not uniform. The distribution ratios are of the same order as those obtained with gelatin, but whereas with gelatin increased phenol uptake was accompanied by precipitation of the protein, with sodium stearate it is associated with the passage of the soap into solution. In each case however the concentration of phenol in the water-phase is directly proportional

to the *square root* of the concentration in the colloid phase, giving then a constant partition-coefficient of about 2. This relationship also holds with the gelatin derivatives, (Tables XVI, XVII, XVIII), and may be associated with the gradual change in the condition of the colloid.

That the soap actually dissolved progressively with rising partition-coefficient is shown in the following experiments carried out in test tubes with 0.5 gm. sodium stearate, 5 c.c. water and 10 c.c. phenol solution. After standing some weeks the solutions were filtered and acidified, the presence of soap in solution being indicated by a precipitate of fatty acid.

3.3	3.33	Heavy ppt.

Although the results are the converse of those obtained in the case of proteins, yet they have an interesting bearing on the interpretation of the relations of phenols to proteins. In the case of both soaps and proteins a change in the physical condition of the colloid can induce significant alterations in their solvent power for phenol, although the two classes of colloids are of quite different chemical nature. The results show the importance of fully considering physical factors in seeking an explanation of the phenomena described in the foregoing pages.

The investigations have shown that phenol and cresol are distributed between water and proteins in the emulsoid state according to the partition law, the partition-coefficient being in general 2-3 times as soluble in the proteins as in the water. At a certain phenol concentration the protein is precipitated, and this change in state is accompanied by an increase in solvent power for phenol, the partition-coefficient rising to about 12. In the case of certain precipitated proteins, e.g. casein, edestin, gliadin, gelatin and its derivatives, with ascending phenol concentration the coefficient of 12, however, continues to increase, thus indicating a further deviation from the partition law, but with precipitated serum albumin, egg-albumin, and pseudo-globulin the partition ratio of 12 remains constant with further increase in concentration. This is also true in the case of heat-coagulæ. Gelatin, however, is precipitated so gradually and over so wide a range of phenol concentration that this in its self may be the explanation of the progressive increase in the partition-coefficient. Nevertheless it is of interest that the phenol concentration in the aqueous phase is directly proportional to the square root of the concentration in the protein phase. The results with casein, gliadin, and edestin, however, are consistent with the view that phenol and cresol become *associated* when dissolved in the precipitated proteins. Thus, when phenol or cresol is dis-

tributed between the solvents, water and benzene, the partition-coefficient $\frac{\text{Concentration of phenol in benzene}}{\text{Concentration of phenol in water}}$ is not constant, but increases with rising phenol concentration, just as is observed with certain precipitated proteins. This apparent deviation from the partition law is due to the association of phenol molecules in the benzene. Phenol, on the other hand, dissolved in a hydroxy-solvent, such as water, consists of simple molecules. Consequently the concentration of phenol in the water phase is no longer directly proportional to the concentration in the associating phase, but to some root of this figure.

As resorcinol is unassociated in benzene, a consideration of the results obtained from a study of the distribution of this dihydroxy phenol between water and gelatin is of some interest.

The Distribution of Resorcinol between Gelatin and Water

Distribution experiments described in the present paper have so far been confined to phenol itself, which on account of its limited solubility, can not be investigated at concentrations above about 7%. Additional experiments have therefore been carried out employing resorcinol in concentrations up to 20%. Like phenol it is a protein precipitant but in conformity with its lower bactericidal power, the precipitating concentration is considerably higher¹.

Estimation of resorcinol

A method similar to that employed for phenol estimation was found to give accurate results.

A volume of concentrated HCl equal to one third the volume of the resorcinol and hypobromite together, is added to the sample. Excess of N/10 sodium hypobromite is run in from the burette, and after the addition of KI, titrated with N/20 sodium thiosulphate and starch. For 10 c.c. of 0.5% resorcinol 40 cc of hypobromite and 4 cc of 20% KI are used and corresponding proportions for other quantities of resorcinol.

The following estimations were carried out with accurately known resorcinol solutions, each made up separately with resorcinol recrystallised from hot benzene.

1. 10 cc 0.100% resorcinol and 6 cc conc. hydrochloric acid required—

8 cc hypobromite	= 0.0602 gm Br
4.15 cc thio.	= 0.0166 gm Br
	0.0436
% resorcinol	= 0.01000×10
	0.100%
2. 10 cc 0.300% resorcinol and 11 cc of acid required—

24 cc hypobromite	= 0.1805 gm Br
12.45 cc thio.	= 0.0497
	0.1308
% resorcinol	= $0.03000 \times 10 = 0.300\%$

¹ Cooper: Biochem. J., 7, 175-196 (1913).

3. 10 cc 0.500% resorcinol and 17 cc acid required—

40 cc hypobromite 0.3008 gm Br

20.8 cc thio. 0.0830

					Mean 4.06

The analyses were carried out after three days except in (5) and (6) where six days were allowed for equilibrium. It is evident that with resorcinol, unlike phenol, precipitation of the protein is not accompanied by an increase in the distribution ratio. In (6) the gelatin had become semi-liquid and was possibly beginning to dissolve. The experiment was therefore repeated using viscose dialysers.

Distribution Experiment B—with Viscose Dialysers

(1) and (2) were analysed after two days and again after five days. (3) was analysed after four and after eight days; (4) was complete in 10 days. The results of the second analyses are shown in brackets beside those of the first.

It is seen that over a wide range of concentration the partition-coefficient averages 4. Resorcinol is thus about twice as soluble as phenol in unprecipitated gelatin, although previous investigations have shown resorcinol to be considerably the weaker germicide and protein precipitant. The bactericidal action of the phenols is thus not merely determined by their actual solubility in proteins, but is apparently due to a subsequent action on the colloidal structure of the bacterial cell.

(3R)	5.54	5.91	0.200	"	3.38	
(3)	10.00	9.23 (9.30)	0.385	"	4.17	
(4)	20.00	19.10 (19.10)	0.45	"	2.36	
	19.77	18.30 (18.75)	0.735	"	4.0	

The results are also of interest inasmuch as, although gelatin is precipitated by resorcinol at 5% concentration, the partition-coefficient does not rise with further increase in concentration, which suggests that the resorcinol dissolved in precipitated gelatin consists of simple molecules, as is the case in benzene.

Although there is thus evidence supporting the view that *phenol* is "associated" in certain proteins, there are difficulties in the way of accepting association as the only factor responsible for the increased solvent power for phenol when a protein is coagulated. Thus, in the case of albumins and globulins coagulated by phenol or heat, when precipitation is complete, the partition-coefficient remains constant at the higher figure of 12 with further rise in phenol concentration. If the phenol were associated in the coagula, the coefficient would be expected to continue to increase as is actually the case with casein and edestin. Furthermore, when phenol is distributed between water and desamino-gelatin, the distribution-ratio also rises with ascending phenol concentration, although this protein contains OH instead of NH₂ groups, and should therefore exert a dissociative action, like water, on the phenol molecular-complexes.

Further research is necessary in order to correlate the two sets of results. It may be concluded however at the present stage that, as the partition law holds in the case of dispersed proteins, the germicidal action of phenol is due not to its molecular association within the emulsoid particles of the bacterial proteins, but rather to its capacity to induce a de-emulsification or precipitation of their colloidal solutions, or probably of one protein in particular, analogous to serum pseudo-globulin, which is precipitated by very low phenol concentrations, of the same order as are known to exert bactericidal action.

THE MECHANISM OF THE ABSORPTION OF WATER BY RUBBER

BY H. H. LOWRY AND G. T. KOHMAN

Rubber compounds as used for purposes of insulation are similar to other substances used for these purposes in that their electrical properties depend to a very great extent upon small amounts of water which are absorbed from the surroundings. In order to make an intelligent attempt to develop an insulating compound from rubber having the best possible insulating properties, it is necessary to have a knowledge of the mechanism by which water is taken up by rubber.

The data in the literature concerning the absorption of water by rubber are incomplete, and the experimental work in general was apparently not planned with the object of throwing light upon the mechanism of water absorption. In most cases the experiments were not carried far enough to enable equilibrium conditions to be predicted and in some cases rates of absorption have been assumed to be proportional to amounts of water absorbed at equilibrium, which, as will be shown, is not always true. Some investigators have studied the absorption of water resulting from contact with pure water only, in which case only information concerning rates can be obtained for a reason which will be made clear later. In order to obtain information concerning the mechanism of water absorption the relations between this process and the following factors were studied:

1. Vapor pressure of water external to the rubber.
2. Water-soluble constituents of the rubber.
3. State of the water external to the rubber (liquid and vapor).
4. Combined sulphur content of the rubber (rigidity).
5. Temperature.
6. Hydrostatic pressure upon the rubber compound.
7. Aging of rubber compounds before and during the process of water absorption.

A number of investigators have observed that rubber compounds absorb appreciable quantities of water and some have investigated the influence of some of the factors dealt with in this paper. It was observed by Hancock¹ in 1876 that a rubber bag filled with 12 ounces of water became empty after a period of thirty years. DeVries² and Whitby³ observed that the water content of raw rubber varied with the humidity of the atmosphere in which it was stored. Van Rossem⁴ and his co-workers, Miss van de Leur and Dekker, have shown that the amount of water absorbed by rubber compounds depends upon the humidity, temperature, and also the amount of water soluble impurities in the rubber. Obach⁵ has studied the absorption of water by

rubber and gutta percha from both fresh water and sea water. He presents data which show that not only do these compounds absorb much less water from sea water than from fresh water, but that the behavior is different in other respects. In fresh water these compounds continue to gain weight even after very long periods of immersion but in sea water they either reach a constant weight or begin losing weight after comparatively short periods of immersion. Whitby¹ has shown that the moisture retaining capacity of raw rubber is closely related to the presence of serum solids which are hygroscopic. Andrews and Johnston² have developed a formula based upon Fick's law of diffusion which is applicable under certain conditions to the rate of absorption of water by rubber compounds. Kirchhof³ has shown that the amount of water absorbed by rubber depends upon the acidity of the rubber and also upon the period of vulcanization. Boggs and Blake⁴ have recently published a paper on the effect of various factors upon the rate of absorption of water by rubber. In a more recent paper Williams and Kemp⁵ discuss the effect of absorbed water on the electrical properties of submarine insulation.

In order definitely to determine the mechanism of water absorption by rubber, a comprehensive study of the process was made, the results of which follow. In making the study it was deemed advisable to eliminate as many complicating factors as possible. The compounds used in the study were therefore in most cases simple rubber sulphur compounds.⁶ To prevent "blooming" of sulphur and consequently changes in weight and composition of the sheet, the period of vulcanization was so regulated that the free sulphur content in most cases was less than one per cent. Certain of the compounds were therefore somewhat over cured.

Experimental Procedure

The method of attacking the problem was to make a study of the various factors which influence the amount and rate of absorption of water. The absorption of water was followed by three methods.

1. In most cases test specimens fifty mils in thickness and two inches on a side were prepared. These test specimens were dried in vacuum, weighed and immersed in solutions of various aqueous vapor pressures. Sodium chloride solutions were used for the most part, partly because Kahlenberg⁷ showed that sodium chloride would not diffuse into rubber, and partly because in certain cases it was desired to obtain information concerning the absorption from sea water. In order to reduce evaporation of the solutions, the

⁴ J. Ind. Eng. Chem., **18**, 224 (1926).

⁵ Williams and Kemp: J. Franklin Inst., **203** (1927).

⁶ Many experiments not reported in this paper have shown that in general the amount of water taken up by filled rubbers, if made free from pores, can be calculated from their rubber content unless the filler itself is either water soluble or hygroscopic.

⁷ J. Phys. Chem., **10**, 141 (1906).

vessels containing the test specimens immersed in solutions of equal vapor pressures were placed in a humidifier, and the solutions were changed periodically to correct for changes in concentration due to the absorption of water by the sheets. The absorption of water was followed by removing the sheets from the solution, washing free from sodium chloride, blotting carefully between sheets of hard filter paper in a standard way, transferring to a weighing bottle and weighing. They were then again immersed in the solution. The blotting and weighing was done as quickly as possible to prevent changes in the moisture content of the sheet. The humidifiers containing the samples at

FIG. 1

25°C . were ordinarily kept in a room the temperature of which was approximately 25°C . In certain cases they were immersed in a thermostat kept at a temperature of $25^{\circ} \pm 0.1$. At temperatures other than 25°C . they were kept in a constant temperature room the temperature of which was controlled by a thermostat to $\pm 1^{\circ}\text{C}$.

2. The absorption was followed by observing the changes in pressure of water vapor in an enclosed system of known volume containing the sample. The apparatus used, shown schematically in Figure 1, is so designed that stopcocks need not be relied upon to prevent leakage. The various systems can be closed or opened by regulating the height of the mercury columns above or below the level D E F by controlling the air pressure above the mercury in the reservoirs R_1 , R_2 and R_3 by means of the two way stopcocks S_1 , S_2 and S_3 which are connected to both a vacuum line and to atmospheric pressure.

The sample in the form of finely cut pieces or very thin sheets is placed in the bulb B and sealed to the apparatus. With the mercury levels at D, H and F, the sample is pumped out by means of mechanical pumps backed by a mercury diffusion pump connected to C. The mercury level of R_1 is then raised to G and that of R_3 to I. The mercury level of R_2 is then slowly lowered

until water vapor furnished by the evaporation of the water in bulb W bubbles past the mercury into the system A. Any desired pressure of vapor can be admitted by following the difference of the mercury levels at I which serve as a manometer. These levels are read to ± 0.03 mm by a micrometer gage¹ not shown. From the volume of the system A and the pressure the amount of water vapor admitted is calculated. The mercury level of R_1 is then lowered to D which allows the water vapor to come in contact with the sample. When the pressure of water vapor in the system has become constant the

pressure is carefully read as before and the amount of water vapor remaining calculated from this pressure and the volume of system A plus that of bulb B and connecting tubing. By repeating these operations as many measurements as are desired can be obtained at pressures from zero to the vapor pressure of water at the temperature of the apparatus. The temperature of the samples was controlled in this case by immersing the bulbs containing the samples in a thermostat, the temperature of which was kept at the specified temperature $\pm 0.2^\circ\text{C}$.

3. A method similar to that used by Miss van de Leur² was used in order to obtain equilibrium values rapidly. The samples in the form of thin sheets or finely cut pieces in weighing bottles were exposed to water vapor above solutions of known vapor pressure until constant weight had been reached. It was found necessary, in order to prevent oxidation of the samples, to use containers which could be pumped free from air after each weighing of samples.

¹ Ferguson: J. Wash. Acad. Sci., 10, 285 (1920).

² Kolloidchem. Beihette, 10, 45 (1918).

The joints of the containers were then sealed with a beeswax-rosin mixture containing 20% rosin. At high relative vapor pressures, (P/P_0 where P is the vapor pressure of water over the solution and P_0 that of pure water), the method was found to be unsatisfactory because of the condensation of moisture on the weighing bottles. The temperature control in this case was the same as that described under method I.

Experimental Results

In Table I A-F are given the average percent weight gains of sheets of various combined sulphur contents after the specified time intervals of immersion in salt solutions of various vapor pressures. The vapor pressures given in the tables are those of the solutions at 25°C. A more complete description of the compounds used is given in Table I F. The data were obtained by method I. The humidifiers in which the sheets were kept were not kept free from air.

In Figs. 2 and 3 the results for sheets No. 5 and 10 of Table I A-E are plotted. The results for the other sheets fall on similar curves. If the water content of each sheet at the end of 210 days be plotted against vapor pressure of the solution in which the sheet was immersed curves of the type shown in Figure 4 are obtained.

There are no experimental determinations on the portions of the curves of Fig. 4 below 18 m.m. because vapor pressures of sodium chloride solutions at 25°C have a lower limit of 17.9 m.m., that being the vapor pressure of a saturated sodium chloride solution. In order to investigate this portion of the curve and also to determine whether or not the vapor pressure of water external to the rubber is the factor which causes the amount of water absorbed

* The rewashed rubber used in these experiments was washed by a special process developed to remove the water soluble constituents from rubber with a minimum amount of physical deterioration. Prior to washing the rubber is passed through a creping mill for 18 minutes during which time it is subjected to a spray of water ranging in temperature between 43 and 52°C. The creped rubber is then washed on a Werner and Pfleiderer washing machine and subjected to a spray of water the temperature of which is lowered from 65 to 45°C during the process. After washing the rubber is again creped to uniform thickness and dried in vacuum.

** In order to reduce the free sulphur content to these values the compounds in some cases were badly over-cured. It was necessary, however, to keep it below approximately one per cent, (the solubility of sulphur in rubber at room temperature) to prevent blooming which would make it impossible to follow the absorption of water by weighing the sample.

by sheets immersed in sodium chloride solutions to decrease as the salt concentration increases, method 2, which enables the absorption to be studied over the entire vapor pressure range, was developed. In Table II the amounts of water absorbed at equilibrium by various samples of rubber as determined by this method are given. The results fall also on curves of the type of that in Fig. 4 as is shown by Fig. 5. Wilson and Fuwa¹ have discussed briefly various types of curves showing the relation between vapor pressure and

amount of water absorbed. The character of the curves such as are shown in Fig. 5 together with other results which will be discussed later have led to a theory of the mechanism of the absorption of water by rubber which has been found to be in harmony with all of the observations concerning this process that have come to the attention of the writers. This theory will be discussed now in order that it may be of help in explaining the results of further experimentation.

It will be observed from Fig. 5 that the solubility of water in rubber at vapor pressures below approximately 16 m.m. at 25° is directly proportional to the first power of the pressure. At these pressures then the solubility obeys Henry's Law and therefore it is probable that the water and rubber form a true solution. Other facts as well point to this conclusion. For example, as is shown by the data plotted in Figs. 2 and 3, the soluble impurities in the rubber do not affect the amount of water absorbed at low vapor pressures appreciably. The sheets from which the soluble impurities have been re-

¹ J. Ind. Eng. Chem., 14, 913 (1922).

moved by washing absorb very nearly as much water as the sheets of commercial rubber at a vapor pressure of 17.9 m.m. while at higher pressures the

soluble impurities have a very noticeable effect. That pores in the rubber are not a factor is shown by the character of the vapor pressure curves. If pores were present in the sheets the water would enter the sheet at constant pressure until they were filled, and therefore the lower parts of the curves of Fig. 5 would deviate from unbroken straight lines. Further evidence that pores do not play a part in water absorption is the fact that rubber sheets, as will be shown later, expand in volume an amount very nearly equal to the volume of water absorbed.

Above a certain vapor pressure (approximately 16 m.m. at 25°C.) the solubility no longer obeys Henry's Law but is much greater than the law would predict, and Figs. 2 and 3 show that this deviation is much greater in the case of commercial rubber than of rewashed rubber. It was, therefore, concluded that when the vapor pressure of water external to the rubber is raised slightly above that of a saturated solution of the water-soluble impurities in the rubber, water diffuses in to form such a solution and then to dilute it until the vapor pressures of the internal and external solutions are equal, the driving force being the vapor pressure difference. If these soluble impurities be washed out, the amount of water absorbed should be reduced to that actually dissolved in the rubber as a lower limit.

The fact that the solubility does not begin to deviate from Henry's Law until the vapor pressure is raised above about 16 m.m. indicates that the gross solubility of the impurities in rubber is such that the vapor pressure of a saturated solution of them is approximately 16 m.m. at 25°C. The theory would lead one to predict that a rubber compound having a single soluble salt as an impurity should show a definite break in the amount of water absorbed with change of vapor pressure or humidity, and also that the curves such as are given in Fig. 5 for compounds containing several different soluble impurities should consist of a series of steps at high relative vapor pressures if the solubility of each impurity were independent of the presence of the other impurities. The effect of one impurity upon the solubility of another, however, probably is sufficient to make the breaks indefinite and impossible of detection. In order to test the theory a compound was prepared of rewashed rubber to which 0.4% of sodium chloride had been added by milling the very finely divided salt into the rubber on a rubber mill. The sheet is identified as compound IX in Table II. The experimental determinations of the amounts of water absorbed at various vapor pressures of water are given in Table III and the absorption curve is shown in Fig. 6. It is evident that below the vapor pressure of a saturated salt solution the curve for the compound made of rewashed rubber in which sodium chloride had been milled is practically identical with that for the compound made of commercial rubber. The latter curve bends at a slightly lower vapor pressure than does the former, indicating that a small amount of a substance having a greater solubility than sodium chloride had been removed from the rubber by washing. When the vapor pressure of water external to the compound is raised slightly above that of a saturated sodium chloride solution a large amount of water enters the com-

15.21	0.24		

pound at constant pressure causing the break in the curve shown in Fig. 6. This water enters the compound very slowly because of the small difference in vapor pressure of the water internal to the compound and that external to it. This difference in pressure is the driving force causing the water to enter the compound. Although the sample was cut in very small pieces a period of four weeks was required for point 2 to be reached. After point 2 has been reached and all of the salt in the compound is in solution, water ceases to enter the sheet until the pressure of water vapor external to the sheet is increased above that of a saturated sodium chloride solution. As the external pressure is increased water will enter the sheet and dilute the internal solution until the vapor pressure of water from this solution is equal to the external pressure.

In order to further check the theory and to determine the feasibility of reducing the amount of water absorbed by rubber compounds by subjecting them to a washing process a sample of raw smoked sheet was washed for periods of from one to five hours. Samples of the rubber were taken at the

end of each hour period of washing and made into 50 mil sheets for water absorption studies. The experimental results presented in table No. 4 are shown graphically in Fig. 7 A. In Fig. 7 B the amount of water absorbed at the end of 200 days is plotted against the time of washing. The results clearly show that the amount of water absorbed decreases with the length of the period of washing.

The water soluble matter in these samples was also determined by a method which is essentially that described by A. van Rossem.¹ Five grams of rubber were cut in small pieces and placed in a pyrex glass extraction apparatus of the type described by T. B. Ford.² The sample was covered with 100 c.c. of distilled water and the apparatus placed on a hot plate regulated to keep the water boiling gently. After a period of eight hours the solution was decanted from the sample, filtered and set aside. The rubber was further extracted with 100 c.c. distilled water in a similar manner for a period of sixteen hours. The solution was again decanted from the sample, filtered and added to the first extract. The combined filtrates were then evaporated to approximately 25 c.c., transferred, together with any solid which had separated, to a platinum dish and evaporated to dryness at 100°C. The residue was then heated to 100°C. until its weight remained constant. In order to correct for the solubility of the glass, blanks were run in an exactly similar manner.

¹ Comm. Delft. 2, 406 (1917); Chem. Abs., 12, 639 (1918).

² J. Am. Chem. Soc., 34, 552 (1912).

Because of the small amounts of material to be extracted the errors in the determinations are large. The results, however, tabulated in Table IV and plotted in Fig. 8 show that the amount of soluble material extracted decreases with length of the washing period from 0.225% to approximately 0.05%. The results tabulated in Table IV and those plotted in Figs. 7 and 8 show also that the sample of unwashed rubber having a high water-soluble content absorbs much more water than do any of the other samples.

It will be noted that there is evidence of a minimum in the graph of Fig. 8 A. The deviations of the points from the curve as drawn are probably within the experimental error, but it is possible that the minimum is real. As the time of washing increases, the tackiness of the rubber increases markedly. Some of the rubber constituents may be redispersed by the long period of extraction and the amount dispersed would naturally increase with the tackiness. An examination of the residue from the extractions indicated the presence of small amounts of rubber. After the extraction has been carried to a certain stage the value of the water extract, as determined above, may therefore reach a minimum value and begin to increase with time of washing even though the amount of water absorbed may decrease continuously.

If equilibrium values be estimated from the curves of Fig. 7 A and plotted against the water extract, the points fall roughly on a straight line as is shown in Fig. 8 B. This straight line, however, does not pass through the origin but indicates that when all of the soluble material is removed from the rubber approximately one percent of water will still be absorbed. This then may be regarded as further evidence that the absorption of water consists of two processes.

The theory as stated would lead one to predict that the absorption of water by sheets of rubber immersed in a solution will be the same as by the same sheets suspended in an atmosphere having a pressure of water vapor equal to the vapor pressure of the solution. In order to confirm this prediction and also to learn whether or not results obtained by the three methods used to follow the absorption are comparable, the absorption of water by sheets of a rubber compound immersed in a 3.5% sodium chloride solution and sheets suspended in the vapor above the same solution was studied. Ten sheets of the following composition:

Commercial Smoked Sheet	95.0%
Combined Sulphur	4.25%
Free Sulphur	0.75%

were immersed in the solution contained in a vacuum humidifier and ten suspended in the vapor above the solution. The humidifier was pumped free from air, sealed with the beeswax-rosin mixture and immersed in a thermostat at 25°C. The humidifier was opened periodically and the sheets weighed. The results of the experiment given in Table V show that both the rate and the amount of absorption are very nearly the same in both cases. The sheets in the vapor apparently contain about 0.25% less water than those in the solution over the entire period. It is believed that this difference represents a surface film which is not removed by the blotting operation in the case of sheets immersed in the solution. The difference between the weights of sheets A and B in Table V becomes slightly less with time, but this may well be due to the extraction of certain constituents of the rubber by the water.

Unless precautions are taken to ensure that the temperature of the sheets in the vapor is the same as that of the sheets in the solution and that the rate of evaporation of the solution is great enough to always keep the surfaces of

the sheets saturated, the results will not be the same in both cases. Very slight differences will cause very great differences in water absorption, particularly at high relative vapor pressures. For example at 25°C a change of temperature of 1° changes the vapor pressure of water nearly 1.5 m.m. and at a relative vapor pressure of 0.98 a change of 1 m.m. in vapor pressure may cause a change of 1% or more in water content in the case of unwashed rubber. This probably is the answer to the question which puzzled Miss van de Leur¹

TABLE V

"why does Hevea sheet in saturated vapor take up 1.85% of water and in pure water 21.5%". A rubber sheet immersed in distilled water should theoretically continue absorbing water indefinitely because the soluble impurities in the rubber sheet will prevent the vapor pressure of the water in the sheet from equaling that of pure water until infinite dilution is reached or until the pressure on the internal solution caused by the resistance of the sheet to swelling increases the vapor pressure of the internal solution sufficiently to make it equal to that of pure water. If the temperature of the sheets in the vapor were only 1°C. above that of the pure water at 25°C. the result would be the same as if the sheets were immersed in a solution of P/P₀ equal to about 0.94. The amounts of water absorbed by a rubber compound in distilled water and in a solution of P/P₀ equal to 0.94 might easily differ by more than the amount observed by Miss van de Leur.

¹ Kolloidchem. Beihefte, 10, 45 (1918).

In certain cases, however, even though every precaution be taken to prevent temperature differences, the amount of water absorbed from the solution will be different from that absorbed from the vapor of the solution. If one of the components of the solution other than the water is soluble in the rubber compound, as will be the case in solutions of ammonia, phenol and certain acids, this compound will be distributed between the water and the rubber. The rubber samples immersed in the solution will, as a result of this distribution, absorb more water than those in the vapor. If soluble material should diffuse from the rubber compound into the solution the effect would be in the opposite direction. However, it would be expected that the amount of water absorbed by the samples immersed in the solution would increase with time to a maximum and finally decrease as the soluble material diffused into the solution.

Sulphur Content—Water Absorption

It might be expected from the theory of the mechanism of water absorption by rubber that the rigidity of a compound would have an appreciable effect upon the amount of water absorbed. Experiments in this laboratory have shown that rubber swells while absorbing water to an extent very nearly equal to the volume of water absorbed. The pressure which the rubber exerts upon the solution internal to the rubber in opposing this swelling will result in an increase in the vapor pressure of the internal solution. Obviously, then an increase in rigidity of the rubber should cause less water to be absorbed than might be expected from the amount of water soluble constituents in the material. If the sulphur during vulcanization had no action upon these water soluble constituents causing them to become insoluble the effect of rigidity could be determined by studying the relation of combined sulphur content (a factor influencing rigidity) to water absorption. The amount of water actually dissolved in the rubber hydrocarbon when exposed to pressures of water vapor below 98% of that of pure water is probably less than one per cent as determined by extending the straight part of the vapor pressure curves and by washing experiments. Therefore the greater part of the water taken up by most rubber compounds is taken up by the soluble impurities in the compounds. The amount of water taken up by these soluble constituents should not be dependent upon the combined sulphur content except as it is affected by the rigidity which the sulphur imparts to the rubber, assuming that the sulphur does not react with the soluble constituents.

In Table VI are tabulated the water contents of sheets of various combined sulphur contents after 7 days and after 210 days immersion in sodium chloride solution of various vapor pressures. The results are shown graphically in Figs. 9 and 10. The amount of water absorbed by the compounds as the combined sulphur content increases does not decrease continuously as might be expected but a break in the curve is apparent at a sulphur content of about 7% even after a period of only 7 days immersion. The break becomes a peak in the curve after longer periods of immersion. It is believed that this peak is caused partly by a slow oxidation of the sheets even when

immersed in solution. Certain other data indicate that the rate of oxidation of straight rubber sulphur compounds is greatest for a combined sulphur content of about 7% and it will be shown later that oxidized rubber absorbs more water than does unoxidized rubber. In the case of sheets sealed up in glass tubes free from air the peak is much less pronounced. The nature of the compound itself is probably also related to the peak in the curve. In many ways rubber of from 6 to 10% combined sulphur differs markedly from either hard or soft rubber.

In spite of this break in the curves the effect of rigidity can be observed in those shown in the Figs. 9 and 10. There is a very great difference in the amount of water absorbed by the rewashed and commercial rubber in the case of rubber having a low combined sulphur content which is very soft. As the sulphur content is increased and the rubber becomes more rigid this difference disappears. The amount of water absorbed by both rewashed and commercial rubber depends to a very great extent upon the vapor pressure of the solution when the sulphur content is low and the rubber is soft and elastic.

When the sulphur content is high and the rubber is very rigid this effect of vapor pressure is very greatly diminished. It will be noted that the amount of water absorbed by the most rigid sheets (highest sulphur content) is even less than that held in true solution by raw rubber or rubber of low combined sulphur content.

The Effect of Temperature upon Water Absorption

The proposed theory would predict that the higher the temperature the greater the rate of absorption of water by a rubber compound since greater differences in vapor pressure of water external and internal differences in vapor pressure of water external and internal to the rubber sheet are possible at higher temperatures and these differences are the driving forces causing water to enter the sheet. Also, rates of diffusion will be higher, the higher the temperature. The theory would also predict that the amount absorbed at equilibrium should not be greatly affected by temperature because the temperature coefficient of vapor pressure is not greatly different for different

solutions and also relative vapor pressure is very nearly independent of temperature, as is shown by the figures of Table VII. If the rigidity of the compounds is appreciably decreased by increasing temperature the amount of water absorbed would be increased. This has been observed for certain thermoplastic compounds and for vulcanized rubber at high temperatures (40-70°C.).

P₀ = Vapor Pressure of Pure Water

P = Vapor Pressure of Solution

The data of Table VII were taken from Landolt-Börnstein: Physikalisch-Chemische Tabellen.

If a sheet of rubber had reached equilibrium at one temperature, a change in temperature would result in a change of vapor pressure of both the solution internal to the rubber sheet and of that external to the sheet. If this change in each case were the same, equilibrium would not be disturbed.

In order to test these conclusions experimentally both the rate of absorption and the equilibrium amounts absorbed by several different rubber compounds were determined at 0°, 15°, 25°, and 40°C. The equilibrium amounts

absorbed at various vapor pressures were first studied by Method (2), the temperature of the thermostat in which the bulbs containing the samples were immersed being regulated to the various temperatures. It is evident that the experiments could not be carried out at pressures of water vapor above that of water at the lowest temperature of the laboratory, which was about 25°C , because condensation of moisture would take place in the apparatus and prevent the pressure being raised above this limit. For this reason the complete vapor pressure curve could not be determined at 40°C .

The results of these experiments are presented in Tables VIII and IX, and those for one compound are shown graphically in Fig. 11. From these it is seen that for a given vapor pressure the amount of water absorbed increases with decreasing temperature, but this does not mean that a sheet of rubber immersed in a salt solution or sea water will absorb less the higher the temperature, as will be evident after studying the figures. It will be noted that if the straight portions of the curves be extended to the line representing the vapor pressure of pure water the intersection for a given sample at the respective temperatures, for example A₁, A₂ and A₃ of Fig. 11A, all lie at the same water content. This means that if relative vapor pressures were plotted instead of absolute vapor pressures the curves for the different temperatures for a single compound would all coincide. The curves of Fig. 11A are plotted in this way in Fig. 11B. As relative vapor pressure is practically independent of temperature, as is shown by Table VII, Fig. 11B should be a single curve within certain limits. These limits are determined by the similarity of the

soluble impurities in rubber to sodium chloride in respect to changes of the relative vapor pressure of their solutions with temperature, and also to change of solubility with temperature.

In order to study the effect of temperature upon the rate of absorption Method (1) was used. The humidifiers were placed in a constant temperature room, the temperature of which was regulated to 0°C + 1°. Method (3) was used to determine equilibrium amounts at 0°. The results of these experiments are presented in Tables X-XIV and representative values plotted in Fig. 12. These results show plainly that the rate of water absorption is higher, the higher the temperature but they also show, that the amount absorbed at equilibrium is not greatly affected. The water content of the

All values given are averages of two values for duplicate samples.

The equilibrium values given in Table XIV show that all of the samples at 0°C. have absorbed more water than the corresponding 50 mil sheets at 25° after a period of 71 days. The results are also in fair agreement with those of

similar sheets immersed at room temperature for a period of 200 days. At the lower vapor pressures (saturated salt solution) where most of the impurities do not have a part in water absorption the agreement is probably within the experimental error. (see Table 1E)

The results of these experiments explain the apparently contradictory results obtained by Miss van de Leur¹ who observed that the amount of water absorbed by rubber compounds from pure water greatly increased with temperature but did not seem to be influenced appreciably at lower relative

vapor pressures. According to the proposed theory the rate of absorption of water increases with temperature, and also compounds immersed in distilled water should continue to absorb water indefinitely. Therefore when sheets of rubber are immersed in distilled water or suspended in the vapor above distilled water the amount of water absorbed after definite time intervals will be greater the higher the temperature. The theory demands and experimental results show that from solutions of P/P_0 below 1, compounds absorb a definite amount of water corresponding to the value of P/P_0 , and that the amount is not greatly dependent upon temperature. Therefore the only effect of an increase in temperature at relative vapor pressures below unity should be an increased rate of approach to equilibrium. In the case of rubber containing a relatively high percentage of water soluble material temperature probably does have a slight effect upon the equilibrium amount of water absorbed as is shown by Figure 12. More water is absorbed at the higher temperature.

¹Kolloidchem. Beihefte 10, 45 (1918).

This is probably caused by a difference in the temperature coefficients of vapor pressure of solutions of the impurities in the rubber and of the solution in which the rubber sheets are immersed.

The "puzzling" results obtained by Obach¹ and commented upon by Kirchoff,² showing that although the temperature of sea water fluctuated

FIG. 13

between 14° and 25°C. , the water content of raw rubber immersed in it remained constant after the first two weeks immersion, also are in accord with the theory and the above experimental results.

The Effect of Hydrostatic Pressure Upon Water Absorption.

Rubber compounds used for submarine insulating purposes are often subjected to considerable hydrostatic pressure. It is of interest therefore, not only from the theoretical but also from the practical standpoint, to know how hydrostatic pressure affects water absorption. To determine this experimentally the pressure bomb illustrated in Fig. 13 was constructed. Sheets of

¹ "Cantor Lectures on Gutta Percha," Appendix VIII, p. 100 (1898).

² Kolloid-Z., 35, 367 (1924).

various rubber compounds were placed in a $3\frac{1}{2}\%$ salt solution in the Tube T, the chamber filled with oil and pressure applied by screwing down the piston P. The pressure used in the experiment was 10,000 lbs. per sq. in. which is equivalent to approximately four miles of hydrostatic pressure. The absorption of water at atmospheric pressure was always determined along with the determinations at high pressure for comparison purposes.

The experimental data are given in Tables XV and XVI and those of Table XVI are plotted in Fig. 14. The results given in the column headed "Differences" are the differences of the average water content of the sheets at atmospheric pressure and 10,000 lbs. pressure. The figures show, as do the curves, that these differences become smaller with time, indicating that the rate of water absorption is slower under the high pressure. The reason for this is probably the effect of pressure upon the density of the rubber compound, causing the rate of diffusion of water in the sheet under pressure to be slower. If this explanation is the correct one, a soft rubber compound would be expected to be affected to a greater extent by hydrostatic pressure than more rigid ones. The results given in Tables XV and XVI show that this is the case. The filled rubber compound is much more rigid than the rubber-sulphur sheet and the values given in the "Difference" column are much larger for the latter than for the former compound.

In order to determine the effect of pressure upon the equilibrium amount of water absorbed several sheets of rubber which had apparently very nearly reached equilibrium at atmospheric pressure were subjected to the high pressure and the change in water content observed. The results are tabulated

in Table XVII and XVIII. They indicate that the effect on the equilibrium amount of water absorbed, if any, will be very small. Those under pressure appear to absorb very slightly the greater amount of water.

The results of the experiments under high hydrostatic pressure are again in harmony with the theory. They are not in agreement however with those of E. Schulze¹ who found that pressures of 150 lbs. per sq. in. increased the amount of water absorbed very greatly. Pressure applied to water or to a solution in such a way that the vapor is free to escape increases the vapor pressure of the water or solution. This increase in the case of water is about one part in one thousand for an increase of pressure of one atmosphere. It is given by the equation $dp/Pd = v/V$ in which p is the vapor pressure of the water, P the externally applied pressure, v the molecular volume of the liquid, and V the molecular volume of the vapor. If the pressure upon the solution in which the rubber sheet is immersed is greater than that upon the solution internal to the rubber the amount of water absorbed should be theoretically increased. The above condition is probably true to a slight extent in the case of porous sheets which are very rigid because the rigidity of the compound would have a tendency to counteract some of the pressure which is exerted upon the external solution. It has been shown, however, by Le Roux² and Terry³ and the writers have found that well-made rubber sheets are not porous.

The amount of water absorbed under pressure would also be increased by the pressure if the volume of the water absorbed by the rubber sheet plus the volume of the dry rubber were greater than the water-rubber solution after absorption. It has been shown by M. Payen⁴ and by Le Roux⁵ that rubber sheets expand in volume to an extent very nearly equal to or probably slightly less than the volume of water absorbed. The writers have also found that the weight of sheets of rubber immersed in a solution and weighed while immersed gain only very slightly in weight which is further evidence that rubber expands in volume very nearly equal to the volume of water absorbed.

The Influence of Aging upon Water Absorption

It will be noted that in certain cases rubber compounds apparently do not reach an equilibrium when immersed in a salt solution. As has already been stated, this might be caused by a change taking place in the sheet with time. In order to determine this and also to determine the effect of aging which is generally agreed to be oxidation, upon the absorption of water by rubber compounds experiments of the following nature were performed:

1. Sheets of a rubber compound were sealed in tubes filled with a salt solution and sheets of the same compound also immersed in solutions in contact with air.
2. Sheets of rubber compound were aged artificially by passing oxygen over the heated sheets and also by heating in an aging oven in air.
3. Sheets of a compound which had previously been studied as regards absorption of water and other properties and which appeared to have aged

⁵ Compt. Rend. 63, 917 (1866).

were redried and again studied in the same manner to determine the effect of any change that had taken place in the sheets.

The results given in Table XIX show the effects of air upon sheets immersed in 3.5% salt solution. The sheets of series A were sealed up in glass tubes filled with the solution which had been pumped free of air before sealing. The sheets of series B were immersed in the same solution contained in wide-mouthed bottles and closed with rubber stoppers. Those of series C were immersed in an open beaker filled with this solution and placed in a large, covered desiccator. It is apparent from the results tabulated in the tables that those sheets with which air could most easily come in contact gain the most in weight.

In order to determine whether or not the peak in the curves representing the amount of water absorbed with variation in sulphur content (Figs. 9 and 10) might be due to an oxidation of the rubber sheets under water which takes place at the greatest rate in the case of rubber compounds of approximately 7% combined sulphur, sheets of rubber were immersed in a 3.5% sodium chloride solution and sealed up in evacuated tubes. Several tubes were prepared and after a tube had once been broken open and the sheets weighed, the sheets were discarded except in the case of the first tube. The sheets in this tube were immersed in a 3.5% sodium chloride solution exposed to the air and weighed periodically. The results of this experiment are shown in Table XX.

The results show that the peak does not appear in case of sheets sealed up in tubes free from air, but in the case of sheets which were not sealed up the amount of water absorbed after 233 days increases rapidly with combined sulphur content up to a sulphur content of 7%. The compounds used in this experiment were made to be as nearly like those used in the experiment shown graphically in Fig. 10B as possible and the experimental results are also in agreement.

Description of Sheets

Sheets A—Unaged

Sheets B—Nitrogen passed over sheets

Sheets C—Oxygen passed over sheets

Sheets D—Aged two weeks at 72°C in Geer Oven.

All values given are the average values of two determinations. The sheets were immersed in a 3.5% sodium chloride solution.

In Table XXI are tabulated data representing measurements made upon sheets of a filled cable compound which had been aged and also upon sheets of the same compound unaged. The aging in this case is artificial. The sheets were placed in an atmosphere of $P/P_0 = 0.98$ in a glass vessel so arranged that it could be heated to 100°C. The vessel was provided with an inlet at the bottom and an outlet at the top for the circulation of oxygen at atmospheric pressure. The sheets were heated in this manner for a period of three hours. For comparison purposes sheets were treated in a similar manner in an atmosphere of nitrogen. It is again apparent from the data of Table XXI plotted in Fig. 15 that the sheets aged in oxygen have taken up more water than those kept free from oxygen.

Sheets of the filled compound used in the previous aging tests were aged two weeks at 72°C. in an oven through which air was circulated (Geer test).

The results of tests made on the aged and unaged material are tabulated in Table XXI and plotted in Fig. 15. It is again apparent that the aging has resulted in an increase in the amount of water absorbed.

In order to determine to what extent aging of rubber compounds which have been kept under water effect the absorption of water, a few representative sheets which apparently had aged as determined by the character of the water absorption curve were redried and reimmersed and the course of the water absorption curve again determined. The data obtained during the first

and second periods of immersion of sheets of a compound composed of re-washed smoked sheet and five percent sulphur are presented in Table XXII and shown graphically in Fig. 16. The course after redrying is very different from the original course as is shown by curves A and B in Fig. 16. If the time origin of curve B is shifted to its proper position relative to the original curve A as shown by curve C it is seen that after a period of ten weeks curve C coincides with the original course of the curve extended.

These results indicate that the rubber compound has aged on the surface during immersion and after the aged sheet has been dried the aged material on the surface and the unaged material absorb water rapidly until saturation has been reached. The water content at this point corresponds to the water content at the end of the first period of immersion plus an additional amount due to additional aging of the sheet. After the aged sheet has become practically saturated the rate of water absorption is again controlled by the rate of

penetration of the film of aged material which determines the slope of the curve. It is possible that the slope of the curve may be of value in studying the aging of rubber compounds.

A surface film of aged material was very noticeable on sheets of the compound used in these experiments. Figure 17 is a photomicrograph of a cross-section of a sheet of the compound after a period of 520 days of immersion showing the film of aged material. The film appears white, probably because it contains a high percentage of water. While all the rubber compounds

studied do not show this effect of aging to such a marked degree, it is believed that this type of aging takes place to some extent in all types of rubber compounds which are exposed to air. Sheets of the same compound immersed in saturated sodium chloride solutions showed only slight evidence of having aged. The explanation of this may be the difference in solubility of oxygen in pure water and in salt solutions.¹

FIG. 17

Photomicrograph of a Cross-Section of an Aged Rubber Sheet.

Magnification—35 diameters.

A. Surface film of aged material on a rubber sheet after a period of 520 days immersion in a salt solution. The white appearance is probably due to a high concentration of absorbed water in the layer.

B. Interior of rubber sheet.

Summary and Conclusions

I. The complete vapor pressure curve for the system water-rubber has been determined for a number of rubber compounds.

II. The absorption of water from both the gaseous and the liquid phase has been studied and found to be the same in both cases provided the constituents other than water present in the phases do not enter the rubber or react with it.

III. It has been shown that washing rubber by a process which is described reduces the amount of water soluble constituents in the rubber and consequently the amount of water absorbed by rubber.

IV. The effect of combined sulphur content of rubber upon the amount of water absorbed has been investigated.

V. The rate of water absorption has been found to increase with temperature but in most cases the amount absorbed is not greatly dependent upon temperature.

VI. Hydrostatic pressure of 10,000 lbs. per sq. in. has been found to reduce the rate of water absorption but to have very little effect upon the amount absorbed at equilibrium.

VII. The amount of water absorbed by rubber compounds has been shown to be increased by a slow aging process which takes place even though the rubber compounds are immersed in solution if air is not excluded. This

¹ According to Fox, (Trans. Faraday Soc., 5, 68 (1909)) the solubility of oxygen in distilled water at 25°C and atmospheric pressure is 0.02887 parts per part of water by volume reduced to N. T. and P. The solubility in a 12% sodium chloride solution under the same conditions, according to Geffcken (Z. physik. Chem., 49, 257 (1904)) is .0145 parts per part of water.

aging takes place to the greatest extent on the surface. Rubber compounds of approximately 7% combined sulphur undergo this aging to the greatest extent.

The facts tabulated above have led to the following conclusions:

I. The most important factor determining the amount of water absorbed by a given sample of rubber is the vapor pressure of water with which it is in equilibrium.

II. The absorption of water by rubber appears to consist of two processes; the formation of a true solution of water in rubber, and the formation of solutions internal to the rubber of water soluble constituents of the rubber which can be removed by washing.

III. Increasing the rigidity of a rubber compound decreases greatly the amount of water absorbed.

INVESTIGATION ON THE HEATS OF COMBUSTION OF PROPOSED SECONDARY STANDARD SUBSTANCES AND ON POSITION AND OPTICAL ISOMERS

BY LEON JEAN PIERRE KEFFLER AND FRANCIS CLINT GUTHRIE

The first aim of the present research has been to investigate the degree of precision that could be obtained for the water equivalent of an adiabatic calorimeter of special design, taking always the same initial and final temperatures for the calorimetric water, so as to make the readings relatively independent of the Beckmann thermometer used. Very concordant results were obtained with a sample of benzoic acid ("100%" pure) supplied by the Bureau of Standards.

The authors therefore considered that they were entitled to proceed.

1. To the determination of the heats of combustion of naphthalene and of salicylic acid and to add their contribution to that of P. Verkaide and J. Coops¹ as to the desirability of the adoption by international agreement of a secondary standard for bomb calorimetry.

2. To the comparison of substances such as position and optical isomers whose heats of combustion are either equal to or only very slightly different from one another.

As the apparatus and method comprise several points, which are new the authors consider it of interest to describe them briefly.

Description of Apparatus and Method

The calorimeter is of the adiabatic submarine type, Fig. 1. It consists of two concentric silver-plated copper vessels, A and B, which are separated by an air gap *c* whose width was chosen as 16 mm. This is within the limits found by White² to correspond to optimum conditions for reducing to a minimum heat transference by conduction and convection. The inner vessel A—the calorimeter proper—weighs 623 grms. and is highly burnished on the outside. The outer vessel B is fitted with a flange at the top and covered with a copper lid D also highly polished on the silver plated lower surface. A water-tight joint was made by means of a rubber washer *w* and eight clamps disposed at equal intervals. The outer edges of the flange and lid were reinforced with stout copper bands E so as to prevent bending by the pressure of the clamps. The communication between the calorimeter proper and the outside was effected by means of four chimneys *a*, *b*, *c*, *d* soldered into the lid. To make the stirring as efficient as possible, the design proposed by Dickinson³ for his non-adiabatic calorimeter was adopted. (see sketch). The whole was completely immersed (except for the four chimneys) in a large cylindrical copper

¹ Rec. Trav. chim., **43**, 567 (1924).

² J. Am. Chem. Soc., **40**, 379 (1918).

³ Bur. Standards Bull., **6**, 189 (1914).

tank F full of water. Adiabatic conditions were obtained by electrolytic heating of this water, according to the method first suggested by Daniels.¹ As the current required was however beyond the limits of safety, the elasticity of the method was considerably increased by the use of a Dewar flask filled with nearly boiling water and communicating by means of rubber tubing with a circular lead pipe, pierced with holes and following the lower contour of the outer vessel. These holes were made of increasing diameter according to their distance from the feed pipe so as to ensure equal distribution throughout the tank. Stirring in the latter was effected by means of two propeller-type stirrers *s* and *s'* symmetrically disposed and driven by the same electric motor.

The heating of the outer vessel, during the rapid rise in temperature which takes place at the beginning of the combustion, was controlled by allowing the hot water to flow in at a steady rate and making the fine adjustment of the temperature by varying the electric heating current. This variation was obtained by rising or lowering a copper sheet triangle in dilute sulphuric acid to the required depth. For maintaining the temperature of the outer jacket when it was several degrees above that of the air, a much smaller current was passed in series with a variable nichrome resistance.

Direct current only being available, neither of the thin copper jackets could be used as anode, as corrosion would have rapidly damaged them. A special anode was therefore constructed of thick copper sheet and shaped in the form of a belt equidistant from both jackets. It was supported on three stout ebonite forks, fitted inside small copper tubes, soldered to the bottom of the outer vessel. To make room for the stirrers, two windows *mn* and *m'n'* were cut in the upper part of the anode.

The inside jacket was supported by means of two diametrically opposed projections *H* and *H'* of the lid which fitted into two fork pieces, *K* and *K'* soldered to the outer jacket. This ensured accurate centering and electrical connection between the two jackets which together constituted the cathode. This arrangement also increased safety in working the apparatus, even with the heavy currents employed, as the anode was well below the surface of the water.

FIG. 1

¹ J. Am. Chem. Soc., 38, 1473 (1916).

The bomb used was of the Berthelot-Mahler type, modified by Kroeker, and its capacity was 283 ccs. It was always evacuated for two minutes before being filled with oxygen, so as to reduce to a minimum the correction corresponding to the formation of nitric acid. The crucible was made of platinum and weighed 9.5 grms. Its dimensions were 25 mms. deep and 25 mms. diam. These were selected after experiments on various forms of crucibles, in view of the fact that no residue of carbon was left in the majority of cases investigated so far.

The comparison between the temperature of the calorimetric water and that of the outside vessel was effected by means of two thermometers graduated in tenths of a degree.

The rise of temperature inside the calorimeter was determined by means of a Beckmann thermometer graduated in hundredths of a degree, and standardised against the hydrogen scale by The National Physical Laboratory. The initial and final points on the scale were illuminated when required by two small electric lamps which, along with an electric hammer, were controlled by separate tapping key switches. Readings were made through a telescope to the nearest 0.0005°C , which corresponds to about two calories.

No Beckmann thermometer is so perfectly constructed as to allow of such a high degree of precision under the normal conditions of use. The concordance of the results first obtained was therefore notably improved by performing all the combustions under exactly the same initial and final conditions of temperature for the calorimeter and jacket. This was effected by weighing always the same amount of a given substance (within a few tenths of a milligram), so as to obtain exactly the same rise in each case.

Just before starting a combustion, the temperature of the calorimetric water was roughly adjusted to within a few tenths of a degree from the constant temperature selected as the starting point (15.38°C) and then brought to the exact value required by means of a specially constructed electric heater, thin enough to pass through one of the chimneys.

After the submarine system was immersed in the outer jacket the temperature of the latter was raised by "electrolytic" heating to the same point as that of the calorimeter. Soon after this equalisation was obtained, the first reading of the Beckmann was taken, then three more after intervals of five minutes. When the rise observed, due to the energy supplied by the stirrer to the calorimetric water, was found to be quite regular, the bomb was fired electrically by means of a platinum wire (.05 mm. diam.). This was wound round a cotton wick in contact with a pellet of the substance to be burnt. A constant weight, 6.3 to 6.5 grms was always taken, and gave thus a practically constant thermal effect, varying from 25 to 25.8 calories. Owing to the fineness of the platinum wire, the heat developed by the ignition current was found to be less than .2 calories and was therefore neglected.

The mercury column of the Beckmann was watched through the telescope so as to enable the supply of heat to the outer vessel to be started as soon as the mercury began to rise.

The uniform distribution of the heat of combustion was always complete after an interval of ten minutes, but the Beckmann was read at intervals of five minutes for a further quarter of an hour, so as to make sure that the rise in temperature per minute due to the friction of the stirrer was the same as that observed just before the ignition took place. This enabled an exact correction to be made for the heat of stirring. On the average this correction amounted to one hundredth of a degree (in ten minutes).

In accordance with the certificate supplied for the Beckmann thermometer by The National Physical Laboratory, a correction of three hundredths of a degree had to be added systematically to the constant range selected (1° to 4°C) in order to reduce it to the hydrogen scale. The water equivalent of the calorimeter was determined by burning six equal quantities of benzoic acid, supplied by the Bureau of Standards, Washington, and guaranteed 100% pure. The heat of combustion was given by the Bureau as 6329 cal. 20° in air (i. e. 6324 cal. 20° in vacuo). For the first two combustions the sample provided was used without drying and for the last four it was carefully dried by heating over an oil bath under reduced pressure.

One cc. of water was always put in the bomb before a combustion. Into the calorimeter were poured 3424 grms. of water (weight in vacuo) having a heat capacity of 3426.3 cal. 20° , at the mean temperature $\frac{1}{2}(15.37 + 18.38) = 16.88^{\circ}\text{C}$ at which all the combustions were carried out. The constancy of the temperature rendered no correction necessary for the variation of the heat capacity with temperature. The pressure used was always 25 atmospheres.

The heat capacity of the calorimeter proper and accessories was found to be equivalent to 325.1 ± 1.6 cal. 20° in vacuo, which gives for the total equivalent of the calorimetric system, the value 3751.4 ± 1.6 cal. 20° in vacuo. The results obtained are summarised in Table I.

The values which appear in the tenth column of that table, as well as in those summarising the experiments on heats of combustion, refer to the correction for unburnt carbon along with that due to carbon monoxide in the very few instances where the latter was found to be present. The determinations of carbon monoxide were made in a large number of cases arbitrarily chosen, but especially when traces of free carbon were apparent. The results obtained for the total correction due to incomplete combustion were small and less than the experimental error in general.

The actual estimation was carried out by passing the bomb gases through a train of potash wash-bottles, a soda-lime tube and a witness tube of baryta solution. The residual gases were then passed through a tube containing copper oxide, heated in an electric furnace and finally absorbed in a measured volume of standard baryta solution in such a manner that the gas stream was broken up into very small bubbles. The carbon monoxide content of the bomb gases was then obtained by titration of the baryta solution.

A test estimation was made on a known amount of carbon monoxide diluted with carbon dioxide and air to about the same extent as in the bomb gases. Analysis gave 11.7 ccs. of CO from 11.9 ccs. originally present.

Maximum deviation from general mean = 2 calories.

Heat of Combustion of Naphthalene

One sample of pure naphthalene, supplied by the British Drug Houses (used for the two first combustions) and another one from Schuckaert (combustions 3 to 6) were both sublimed twice at the lowest possible temperature under reduced pressure. The results obtained are summarised in Table II.

This corresponds to the value 9606 cal. 20° per gram in vacuo (at constant volume). These results agree well with those obtained recently by Dickinson, Richards and Davis,¹ Swientoslawski,² and Verkade,³ as is shown clearly in Table III. In this table, for the sake of comparison the heats of combustion have been expressed in cal. 20°. The values obtained by the same observers for the ratio of the heat of combustion of naphthalene to that of benzoic acid are given in the fifth column.

Heat of Combustion of Salicylic Acid

The purest specimens obtainable from the British Drug Houses (see the first two combustions) and from Schuckaert (combustions 3 to 5) were both recrystallised three times from absolute alcohol, then from distilled water. After drying over calcium chloride and phosphoric anhydride in succession, they were recrystallised from heptane. The last traces of solvent were removed by heating in steam under reduced pressure. A third sample obtained from Poulenc Frères, and said to be the same as that used by Verkade and Coops⁴ was first experimented upon without further purification (combustions 6 to 8). After crystallising from ether and freeing from any solvent by heating in vacuo, and finally drying by heating over phosphoric anhydride, a new group of combustions was obtained (combustions 9 to 11). The results are given in Table IV.

This corresponds to the value 5239 cal. 20° per gram in vacuo (at constant volume). These results are midway between those obtained recently, on the one side by Swientoslawski⁵, Verkade⁶, Roth⁷ with a Beckmann thermometer, and on the other side by Berner⁸ with a platinum resistance thermometer,

Maximum deviation from general mean = 1.9 calories.

and which are respectively 5242.4, 5242.0, 4251.3, 5237.4, cal. 15° per gram weighed in air. The deviation of our mean results from theirs is just of the order of accuracy which can be expected with a Beckmann thermometer. (According to a private communication from the National Physical Laboratory a Beckmann thermometer can only be standardised to within 0.002°C . some thermo-chemists claim however that an accuracy of 0.001°C can be reached.) As Verkade has checked his own Beckmann thermometer against that of Roth and found both agreed very well with one another, it is to be expected that their values for the heat of combustion of a substance such as salicylic acid (the purification of which has been carried out beyond doubt to the utmost limits of refinement by such thermochemical experts) should be in very good agreement.

The ratios obtained by the above mentioned observers for the heat of combustion of benzoic acid to that of salicylic acid are given in the Table V in the order of increasing values.

The Heat of Combustion of Meta and Para Hydroxybenzoic Acids

The samples supplied by Poulenc Frères showed signs of oxidation, and were therefore dissolved in boiling water, in presence of ignited animal charcoal, whilst passing in a current of sulphur dioxide. On filtering and cooling crystals separated and these were recrystallised from water, twice in the case of the meta and six times in the case of the para compound. (After many trials, water was found to be the best solvent). While, finely crystallised products were ultimately obtained, and these were dried over steam under reduced pressure. Table VI summarises the results.

The heats of combustion of o-, m-, and p-hydroxybenzoic acids are thus 5243.1 ± 1.9 , 5244.2 ± 1.5 , 5237.8 ± 2.1 cal. 20° per gram weighed in air, whilst those found by Stohmann¹ in 1899 were respectively 5287, 5283 and 5260 calories.

This seems to indicate that at least some of the relatively large differences which are found in the literature between the heats of combustion of position isomers might be ascribed to insufficient purification and especially to inaccuracy of the calorimetric methods as used some thirty years ago.

General mean = 5237.8 cal₂₀ per gram weighed in air.

Maximum deviation from general mean = 2.1 calories.

The Heat of Combustion of Dextro and Laevo Borneols

Both were obtained from the British Drug Houses and recrystallised several times from alcohol and then from heptane and finally dried by heating over an oil bath under reduced pressure.

The purification was continued until polarimetric measurements gave the constant molecular rotation $[\alpha]_D^{25} = +31^\circ$ and $[\alpha]_D^{25} = +38^\circ 7'$, using heptane as a solvent. The results obtained are shown in Table VII.

Summary

A. An adiabatic calorimeter with some new features has been described and this has given complete satisfaction.

2. With a mercury-in-glass thermometer, a greater precision in the measurement of heats of combustion is claimed as the result of the introduction of a new method consisting in selecting for all combustions almost exactly the same initial and final points on the Beckmann scale. This procedure giving a constant mean for the temperature of the calorimetric water, simplifies the calculations by rendering constant the otherwise variable correction for the specific heat of the water and of the metallic parts of the calorimeter.

It has also the great advantage of making all the readings independent of errors in the scale between the standardised points. With benzoic acid, for example, the maximum deviation from the general mean was thus improved from ± 10 to ± 1.6 calories.

3. The results obtained for the heats of combustion of naphthalene and salicylic acid show by their great concordance that both are very suitable as secondary standards for bomb calorimetry, although salicylic acid is perhaps slightly better owing to its lower volatility.¹

4. The consideration of the heats of combustion of the ortho-meta- and para-hydroxy derivatives of benzoic acid leads to the conclusion that the energy contents of the ortho and meta derivatives are the same within the limits of experimental error, whilst a very slight difference, of the order of about three times the experimental error, is indicated in the case of the para compound as compared to the ortho- and meta-isomers.

5. The values obtained for the two optically active forms of borneol show that there is no energy change involved in the transformation of the one form into the other.

The authors wish to thank Professor E. C. C. Baly F. R. S. for the facilities he has kindly placed at their disposal for carrying out this work. They feel also greatly indebted to Professor Bannister for the bomb he has kindly lent to them.

THE MASS UNIT OF THE CHEMICAL POTENTIAL

BY WILDER D. BANCROFT

It may be carrying coals to Newcastle to explain selected passages from Gibbs to the chemists; but I have found no chemists—either hand-picked or run-of-mine—who would explain them to me and consequently I feel temporarily like a discoverer, quite regardless of whether I am one or not. For the sake of convenience the references are to the first volume of "The Collected Papers of J. Willard Gibbs," edited by H. A. Bumstead and R. G. Van Name.

"If we consider the amount and kind of matter in a homogeneous mass as fixed, its energy is a function of its entropy η , and its volume v and the differentials of these quantities are subject to the relation

$$d\epsilon = td\eta - pdv, \quad (11)$$

t denoting the (absolute) temperature of the mass, and p its pressure. For $td\eta$ is the heat received, and pdv the work done by the mass during its change of state. But if we consider the matter in the mass as variable, and write m_1, m_2, \dots, m_n for the quantities of the various substances S_1, S_2, \dots, S_n of which the mass is composed, ϵ will evidently be a function of $\eta, v, m_1, m_2, \dots, m_n$, and we shall have for the complete value of the differential of ϵ

$$d\epsilon = td\eta - pdv + \mu_1 dm_1 + \mu_2 dm_2 \dots + \mu_n dm_n, \quad (12)$$

$\mu_1, \mu_2, \dots, \mu_n$ denoting the differential coefficients of ϵ taken with respect to m_1, m_2, \dots, m_n .

"The substances S_1, S_2, \dots, S_n , of which we consider the mass composed, must of course be such that the values of the differentials dm_1, dm_2, \dots, dm_n shall be independent, and shall express every possible variation in the composition of the homogeneous mass considered, including those produced by the absorption of substances different from any initially present. It may therefore be necessary to have terms in the equation relating to component substances which do not initially occur in the homogeneous mass considered, provided, of course, that these substances, or their components, are to be found in some part of the whole given mass.

"If the conditions mentioned are satisfied, the choice of the substances which we are to regard as the components of the mass considered may be determined entirely by convenience, and independently of any theory in regard to the internal constitution of the mass. The number of components will sometimes be greater, and sometimes less, than the number of chemical elements present. For example, in considering the equilibrium in a vessel containing water and free hydrogen and oxygen, we should be obliged to recognize three components in the gaseous part. But in considering the equilibrium of dilute sulphuric acid with the vapor which it yields, we should have only two components in the liquid mass, sulphuric acid (anhydrous, or of any particular degree of concentration) and (additions) of water. If, however, we are considering sulphuric acid in a state of maximum concentra-

tion in connection with substances which might possibly afford water to the acid, it must be noticed that the condition of the independence of the differentials will require that we consider the acid in the state of maximum concentration as one of the components. The quantity of this component will then be capable of variation both in the positive and in the negative sense, while the quantity of the other component can increase but cannot decrease beyond the value zero.

"For brevity's sake, we may call a substance S_a an *actual component* of any homogeneous mass, to denote that the quantity m_a of that substance in the given mass may be either increased or diminished (although we may have so chosen the other component substances that $m_a = 0$); and we may call a substance S_b a *possible component* to denote that it may be combined with, but cannot be subtracted from the homogeneous mass in question. In this case, we must so choose the component substances that $m_b = 0$.

"The units by which we measure the substances of which we regard the given mass as composed may each be chosen independently. To fix our ideas for the purpose of a general discussion, we may suppose all substances measured by weight or mass. Yet in special cases, it may be more convenient to adopt chemical equivalents as the units of the component substances," p. 63.

"If we call a quantity μ_x , as defined by such an equation as (12), the potential for the substances S_x in the homogeneous mass considered, these conditions may be expressed as follows—*The potential for each component substance must be constant throughout the whole mass*," p. 65.

"Whenever, therefore, each of the different homogeneous parts of the given mass may be regarded as composed of some or all of the same set of substances, no one of which can be formed out of the others, the condition which (with equality of temperature and pressure) is necessary and sufficient for equilibrium between the different parts of the given mass may be expressed as follows:—

"The potential for each of the component substances must have a constant value in all parts of the given mass of which that substance is an actual component, and have a value of not less than this in all parts of which it is a possible component," p. 67.

"In the definition of the potentials μ_1, μ_2 , etc., the energy of a homogeneous mass was considered as a function of its entropy, its volume, and the quantities of the various substances composing it. Then the potential for one of these substances was defined as the differential coefficient of the energy taken with respect to the variable expressing the quantity of that substance. Now as the manner in which we consider the given mass as composed of various substances is in some degree arbitrary, so that the energy may be considered as a function of various different sets of variables expressing quantities of component substances, it might seem that the above definition does not fix the value of the potential of any substance in the given mass, until we have fixed the manner in which the mass is to be considered as composed. For example, if we have a solution obtained by dissolving in water a certain salt containing

water of crystallization, we may consider the liquid as composed of m_s weight units of the hydrate and m_w of water or as composed of m_a of the anhydrous salt and m_w of water. It will be observed that the values of m_s and m_a are not the same, nor those of m_w and m_w , and hence it might seem that the potential for water in the liquid considered as composed of the hydrate and water, viz.,

$$\left(\frac{d\epsilon}{dm_w} \right)_{\eta, v, m_s},$$

would be different from the potential for water in the same liquid considered as composed of anhydrous salt and water, viz.,

$$\left(\frac{d\epsilon}{dm_w} \right)_{\eta, v, m_a},$$

The value of the two expressions is, however, the same, for, although m_w is not equal to m_w , we may of course suppose dm_w to be equal to dm_w , and then the numerators in the two fractions will also be equal, as they each denote the increase of energy of the liquid, when the quantity dm_w or dm_w of water is added without altering the entropy and volume of the liquid. Precisely the same considerations will apply also to any other case. In fact, we may give a definition of a potential which shall not presuppose any choice of a particular set of substances as the components of the homogeneous mass considered.

Definition.—If to any homogeneous mass we suppose an infinitesimal quantity of any substance to be added, the mass remaining homogeneous and its entropy and volume remaining unchanged, the increase of the energy of the mass divided by the quantity of the substance added is the *potential* for that substance in the mass considered. (For the purposes of this definition, any chemical element or combination of elements in given proportions may be considered a substance, whether capable or not of existing by itself as a homogeneous body," p. 92.

"Between the potentials for different substances in the same homogeneous mass the same equations will subsist as between the units of these substances. That is, if the substances, S_a, S_b , etc. S_k, S_l , etc., are components of any given mass, and are such that

$$\alpha S_a + \beta S_b + \text{etc.} = \kappa S_k + \lambda S_l + \text{etc.}, \quad (120)$$

S_a, S_b , etc., κ, λ , etc., denoting numbers, then if μ_a, μ_b , etc., μ_k, μ_l , etc., denote the potentials for those substances in the homogeneous mass.

$$\alpha \mu_a + \beta \mu_b + \text{etc.} = \kappa \mu_k + \lambda \mu_l + \text{etc.} \quad (121)$$

To show this, we will suppose the mass considered to be very large. Then the first member of (121) denotes the increase of the energy of the mass produced by the addition of the matter represented by the first member of (120), and the second member of (121) denotes the increase of energy of the same mass produced by the addition of the matter represented by the second member of (120) the entropy and volume of the mass remaining unchanged in each case. Therefore, as the two members of (120) represent the same matter in kind and quantity, the two members of (121) must be equal.

"But it must be understood that equation (120) is intended to denote equivalence of the substances represented *in the mass considered*, and not merely chemical identity; in other words, it is supposed that there are no passive resistances to change in the mass considered which prevent the substances represented by one member of (120) from passing into those represented by the other. For example, in respect to a mixture of vapor of water and free hydrogen and oxygen (at ordinary temperature), we may not write

$$9 S_{Aq} = 1 S_H + 8 S_O$$

but water is to be treated as an independent substance, and no necessary relation will subsist between the potential for water and the potentials for hydrogen and oxygen," p. 94.

If we work at temperatures at which the reaction of hydrogen and oxygen to form water is a reversible one or if we produce a state of reversible equilibrium by the addition of a suitable catalytic agent (pp. 139, 141, 184), then we can write

$$\begin{aligned} 9 S_{Aq} &= 1 S_H + 8 S_O \\ \text{or} \quad 9 \mu'_{Aq} &= 1 \mu'_H + 8 \mu'_O. \end{aligned}$$

Gibbs says, p. 363, that "when the proximate components of a gas-mixture are so related that some of them can be formed out of others, although not necessarily in the gas-mixture itself at the temperatures considered, there are certain phases of the gas-mixture which deserve especial attention. There are the *phases of dissipated energy*, i.e., those phases in which the energy of the mass has the least value consistent with its entropy and volume. An atmosphere of such a phase could not furnish a source of mechanical power to any machine or chemical engine working within it, as other phases of the same matter might do. Nor can such phases be affected by any catalytic agent. A *perfect catalytic agent* would reduce any other phase of the gas-mixture to a phase of dissipated energy. The condition which will make the energy a minimum is that the potentials for the proximate components shall satisfy an equation similar to that which expresses the relation between the units of weight of these components. For example, if the components were hydrogen, oxygen, and water, since one gram of hydrogen with eight grams of oxygen are chemically equivalent to nine grams of water, the potentials for these substances in a phase of dissipated energy must satisfy the relation"

$$9 \mu'_{Aq} = 1 \mu'_H + 8 \mu'_O$$

If we express these units in gram-molecular weights, as chemists usually do, we shall write for a phase of dissipated energy, which is another way of saying a state of reversible equilibrium,

$$2 \mu_{H_2O} = \mu_{H_2} + \mu_{O_2}$$

where μ' is the chemical potential referred to grams and μ the chemical potential referred to molecular weights. In order to avoid confusion, Lash Millor suggests using the words specific potential for the chemical potential referred to grams, the molecular potential (or mol-potential) for the chemical potential referred to molecular weights, and the equivalent potential for the

chemical potential referred to equivalent weights. The coulomb potential might be used for the chemical potential referred to the electrochemical equivalent.

This is a bit puzzling to the chemist, especially if he wishes to deduce the mass law from the relation between the potentials at equilibrium. The difficulty is due to the fact that Gibbs defines the chemical potential in a purely formal way.

"The potential for any substance in any homogeneous mass is equal to the amount of mechanical work required to bring a unit of the substance by a reversible process from the state in which its energy and entropy are both zero into combination with the homogeneous mass, which at the close of the process must have its original volume, and which is supposed so large as not to be sensibly altered in any part. All other bodies used in the process must by its close be restored to their original state, except those used to supply the work, which must be used only as the source of the work. For, in a reversible process, when the entropies of other bodies are not altered, the entropy of the substance and mass taken together will not be altered. But the original entropy of the substance is zero; therefore the entropy of the mass is not altered by the addition of the substances. Again, the work expended will be equal to the increment of the energy of the mass and substance taken together, and therefore equal, as the original energy of the substance is zero, to the increment of energy of the mass due to the addition of the substance, which by the definition on p. 93 is equal to the potential in question," p. 95.

Under this definition the potential of any given substance is a function of the mass unit adopted. The molecular chemical potential or the chemical potential of a gram-molecular weight of oxygen taken as the mass unit is thirty-two times of the specific chemical potential or the potential of the same amount of oxygen with one gram taken as the mass unit. In other words $\mu_{H_2} = 2\mu'_H$, $\mu_{O_2} = 32\mu'_O$ and $\mu_{H_2O} = 18\mu'_{Aq}$. Substituting these values in the equation $2\mu_{H_2O} = 2\mu_{H_2} + \mu_{O_2}$, we get $36\mu'^{Aq} = 4\mu_H + 32\mu_O$ or $9\mu'_{Aq} = 1\mu'_H + 8\mu'_O$.

Lash Miller points out that when hydrogen, oxygen and water are in a state of reversible equilibrium, the following three equations all say exactly the same thing:—

$$\begin{aligned} 9 \times \text{specific potential water} &= 8 \times \text{specific potential oxygen} \\ &+ \text{specific potential hydrogen} \\ 2 \times \text{molecular potential water} &= \text{molecular potential water} \\ &+ 2 \times \text{molecular potential hydrogen} \\ \text{Equivalent potential water} &= \text{equivalent potential oxygen} \\ &+ \text{equivalent potential hydrogen.} \end{aligned}$$

All these equations are identical under the formal definition of the potential. The question then arises whether this definition is a desirable one in the general form which Gibbs has given it. I have not yet found that Gibbs has discussed this question definitely anywhere. Really the mass unit to be taken for the chemical potential should be the one which is the chemical unit for the process under consideration, because this is the one which leads

directly to the mathematical formulas describing the equilibria. When we are considering pressure-volume-temperature relations for gases, the obvious units are the molecular weights. Ignoring variations from the gas law, two grams of hydrogen are equivalent to thirty-two grams of oxygen, eighteen grams of water, or thirty-six and a half grams of hydrochloric acid. So far as I can see, it is quite impossible to pass directly from the relation $9\mu'_{\text{Aq}} = 1\mu'_{\text{H}_2} + 8\mu'_{\text{O}_2}$ to the equation $\text{KC}^2\text{H}_2\text{O} = \text{C}^2\text{H}_2 \cdot \text{C}_2\text{O}_2$. We must pass through the relation $2\mu_{\text{H}_2\text{O}} = 2\mu_{\text{H}_2} + \mu_{\text{O}_2}$. When considering mass law relations, we must, therefore, refer the chemical potentials to the molecular weights as units. Gibbs actually does this, p. 362, and assumes that we shall follow him.

"From the physical properties which we attribute to ideal gases, it is easy to deduce their fundamental equations. The fundamental equation in ϵ , η , v and m for an ideal gas is

$$c \log \frac{\epsilon - \text{Em}}{\text{cm}} = \frac{\eta}{m} + H + a \log \frac{m}{v}; \quad (17)$$

that in ψ , t , v , and m is

$$\psi = \text{Em} + mt (c - H - c \log t + a \log m/v). \quad (18)$$

that in p , t and μ is

$$p = ae^{\frac{H-c-a}{a}} t^{\frac{c+a}{a}} e^{\frac{\mu-F}{at}} \quad (19)$$

where e denotes the base of the Naperian system of logarithms. As for the other constants, c denotes the specific heat of the gas at constant volume, a denotes the constant value of $p v \div m t$, E and H depend upon the zeros of energy and entropy. The two last equations may be abbreviated by the use of different constants. The properties of fundamental equations mentioned above may easily be verified in each case by differentiation.

"The law of Dalton respecting a mixture of different gases affords a point of departure for the discussion of such mixtures and the establishment of their fundamental equations. It is found convenient to give the law the following form:—

"The pressure in a mixture of different gases is equal to the sum of the pressures of the different gases as existing each by itself at the same temperature and with the same value of its potentials."

If we take the logarithm of equation (19) and consider the temperature as constant, we get

$$\mu = at \log p + \text{constant}$$

which is identical with the one that the modern physical chemist would write,

$$\mu = RT \log p + C.$$

If we express the chemical potentials in terms of molecular weights, as mass units, the relation for the reversible equilibrium between hydrogen, oxygen, and water becomes $2\mu_{\text{H}_2} + \mu_{\text{O}_2} = 2\mu_{\text{H}_2\text{O}}$

or, in terms of pressures,

$$2 RT \log p_1 + 2 C_1 + RT \log p_2 + 2 \log C_2 = 2 RT \log p_3 + 2 C_3,$$

which reduces to

$$p_1^2 \cdot p_2 = K p_3^2,$$

the regular mass law equation for this case.

If we are dealing with electromotive forces, Gibbs has shown that the electromotive force of a reversible cell is a measure of the difference of the chemical potentials. If we take the gram as the mass unit, the electromotive force is proportional to the difference of the specific chemical potentials. If we take the electrochemical equivalent as the mass unit, the electromotive force is equal to the difference of the coulomb chemical potentials, p. 331.

"We know by experience that in certain fluids (electrolytic conductors) there is a connection between the fluxes of the component substances and that of electricity. The quantitative relation between these fluxes may be expressed by an equation of the form

$$De = \frac{Dm_a}{\alpha_a} + \frac{Dm_b}{\alpha_b} + \text{etc.} - \frac{Dm_g}{\alpha_g} - \frac{Dm_h}{\alpha_h} + \text{etc.}, \quad (682)$$

where De , Dm_a , etc. denote the infinitesimal quantities of electricity and of the components of the fluid which pass simultaneously through any same surface, which may be either at rest or in motion, and α_a , α_b , etc., α_g , α_h , etc. denote positive constants. We may evidently regard Dm_a , Dm_b , etc., Dm_g , Dm_h , etc. as independent of one another. For, if they were not so, one or more cou'd be expressed in terms of the others and we could reduce the equation to a shorter form in which all the terms of this kind would be independent.

"Since the motion of the fluid as a whole will not involve any electrical current, the densities of the components specified by the suffixes must satisfy the relation.

$$\frac{\gamma_a}{\alpha_a} + \frac{\gamma_b}{\alpha_b} + \text{etc.} = \frac{\gamma_g}{\alpha_g} + \frac{\gamma_h}{\alpha_h} + \text{etc.} \quad (683)$$

These densities, therefore, are not independently variable, like the densities of the components which we have employed in the other cases.

"We may account for the relation (682) by supposing that electricity (positive or negative) is inseparably attached to the different kinds of molecules, so long as they remain in the interior of the fluid, in such a way that the quantities α_a , α_b , etc. of the substances specified are each charged with a unit of positive electricity, and the quantities α_g , α_h , etc. are each charged with a unit of negative electricity. The relation (683) is accounted for by the fact that the constants α_a , α_g , etc. are so small that the electrical charge of any sensible portion of the fluid varying sensibly from the law expressed in (683) would be enormously great, so that the formation of such a mass would be resisted by a very great force.

"It will be observed that the choice of the substances which we regard as the components of the fluid is to some extent arbitrary and that the same physical relations may be expressed by different equations of the form (682), in which the fluxes are expressed with reference to different sets of components. If the components chosen are such as represent what we believe to be the actual molecular constitution of the fluid, those of which the fluxes appear in the equation (682) are called the *ions* and the constants of the equation are called their *electro-chemical equivalents*. For our present purpose, which

has nothing to do with any theories of molecular constitution, we may choose such a set of components as may be convenient, and call those *ions*, of which the fluxes appear in the equation of the form (682) without farther limitation."

When we let V' , V'' denote the electrical potentials in pieces of the same metal connected with the two electrodes of a reversible cell, "when the great effect of gravity may be neglected and when there are but two electrodes, as in a galvanic or electrolytic cell, we have for any cation

$$V'' - V' = \alpha_a (\mu_{\alpha'} - \mu_{\alpha''}) \quad (687)$$

and for any anion

$$V'' - V' = \alpha_g (\mu_{g''} - \mu_{g'}) \quad (688)$$

where $V'' - V'$ denotes the electromotive force of the combination. That is:—

"When all the conditions of equilibrium are fulfilled in a galvanic or electrolytic cell, the electromotive force is equal to the difference in the values of the potential for any ion or apparent ion at the surfaces of the electrodes multiplied by the electrochemical equivalent of that ion, the greater potential of an anion being at the same electrode as the greater electrical potential, and the reverse being true of a cation," p. 332.

Gibbs thus states explicitly that we can refer the chemical potentials to grams or to electrochemical equivalents and that the second is simpler because then equations (687) and (688) become

$$V'' - V' = (\mu)_{\alpha'} - (\mu)_{\alpha''} \text{ and } V'' - V' = (\mu)_{g''} - (\mu)_{g'}.$$

Actually, we do not use either of these expressions, because we are concerned with the osmotic pressure of the ions and consequently we refer the chemical potentials to gram ions and bring the valence of the ion in elsewhere in the formula. This gives $nF(V'' - V') = (\mu)' - (\mu)_{\alpha''} = (\mu)_{g''} - (\mu)_{g'}$. For the single potential difference at the surface of an electrode reversible with respect to the cation, this becomes

$$nFE = \mu_m - \mu_s = RT \log P/p,$$

which is the Nernst equation, μ_m being the potential of the metal and μ_s the potential of the cation in solution.

The measurement of an electromotive force, as usually carried out, does not involve the measurement or knowledge of the current in any portion of the apparatus, except that there must be no current flowing through the telephone, galvanometer, or electrometer. Since the value of the coulomb chemical potential will depend on the value assumed for the coulomb, it may seem to some that the electromotive force, which is apparently independent of the value of the coulomb cannot necessarily be a measure of the coulomb chemical potential. This is an error, because the value of the ampere (coulomb per second), the volt, and the ohm are so connected by Ohm's law that we have only two independent variables. If we keep the ohm constant and vary the value of the coulomb, we shall necessarily change the value of the volt. While it might be possible on paper to keep the unit of potential difference constant and to vary simultaneously the ohm and the coulomb, this is not practical, however, because we have a relation between the joule (volt-coulomb) and the calorie, so that we cannot very well vary the coulomb

without varying the volt. Actually, this discussion is academic because nobody has any intention of doubling or halving the value of the coulomb.

It may be asked what the use of this whole paper is when Gibbs has already stated clearly that the chemical potential may be referred to any mass unit, meaning thereby that in equations one may use specific potentials, molecular potentials, etc., provided one introduces in each case the appropriate factors. One reason for writing this paper is that Ostwald has apparently never been clear on the question of the mass unit and it is probable that others have been equally confused. I know that I have been.

In an early paper Ostwald¹ gives the combining weight as the capacity factor of chemical energy and says that "the capacity factor of the chemical energy, like that of heat is proportional to the mass and the weight. From the name for it, the combining weight, one must not conclude that the chemical capacity is fundamentally a weight. It is not that any more than it is a mass. It is only proportional to these two and the proportionality factor changes with the nature of the substance. A 'dimension' in the usual units of length, time, and mass can no more be given for the capacity factor of chemical energy than for any of the other energy factors of the table; all assumptions to the contrary rest on arbitrary omissions and therefore on error."

A little later there is a paragraph² which may or may not have a bearing. "It must finally be mentioned that several capacity factors are equal for chemically comparable amounts of different substances. This was first suggested by LeChatelier and was emphasized strongly by Meyerhoffer³. Thus the value R of the gas equation $PV = RT$ is the same for molecular amounts, the heat capacity for atomic weights, and the electrochemical capacity for equivalent weights. These three examples show, however, that the weights in question are not proportional from case to case, for the gas content, the heat capacity, and the electrochemical capacity are proportional respectively to the molecular weight, the atomic weight, and the electrochemical equivalent, and these are not in general proportional for different substances. Other capacities, such as the mass, do not show the relation and consequently the rule is by no means general."

On page 500 of the same volume, Ostwald says: "While the intensity factor of heat, the temperature, is well known to us and the other factor, the entropy, is difficult to grasp, the converse is true in the case of the chemical energy. It appears to us so obvious that the chemical energy is proportional to the amount of the substances in question, other things being equal, that at first we do not trouble to formulate such a hypothesis. Nevertheless, it is necessary to be clear that this proportionality of chemical energy to mass and weight is an empirical fact, not in any way necessary *a priori*. Mass is a magnitude which belongs only in the field of kinetic energy and is connected with chemical energy only through this proportionality law. This latter holds

¹ Z. physik. Chem., 10, 370 (1892).

² Lehrbuch allgem. Chemie, 2 I, 50 (1893).

³ Z. physik. Chem., 7, 544 (1891).

also for weight. In addition, we know from experience that the proportionality factor depends to a great extent on the special (chemical) nature of the substances.

"The factor of the chemical energy which is proportional to the mass of the substances in question, does not have the character of an intensity because it determines neither the occurrence nor the form of the chemical changes. We shall, therefore, have to set the chemical capacity proportional to the mass. It is not desirable to make the proportionality factor between the mass and the chemical capacity equal to unity and thus refer the chemical energy to the unit of mass of the different substances as happened in the earlier development of thermochemistry. The law of combining weights suggests to us to multiply the values referred to the unit of mass by combining weights and thereby to evaluate the chemical energy for such quantities of different substances which stand in the ratio of the combining weights. In this way the necessary calculations are reduced to a minimum and the relations between the chemical energy of different substances are easier to see."

On p. 502 Ostwald says: "In regard to the choice of the chemical capacity factor we have to make a definite, more or less arbitrary, agreement, just as we had to do in regard to the chemical combining weights. In that case it was possible so to determine these latter values that a number of other relations assume a simple and clear form, whereby a definite system of values, the atomic weights now in use, have proved the most serviceable in every way. Since the numerical values of the chemical capacity factors have no other condition to satisfy than that their sum for the substances and the amounts of the substances shall be equal on both sides of a chemical equation for the reaction, a condition which the atomic and combining weights satisfy, *we may take these values as the units of the chemical capacity for the different substances.*"

All this is a bit vague, but it seems to mean that the combining weights are the mass units for the chemical capacity factor. This does not seem to me to be right at all. Gibbs has shown that in a completely reversible voltaic cell the electromotive force is a measure of the chemical potential (or rather of the difference of chemical potential) when we take as the mass unit the electrochemical equivalent, which is quite a different thing from the equivalent weight, the latter being approximately 96500 times the former. On the other hand, we must take the molecular weights as the mass units if we are to deduce the mass law directly from the relation between the chemical potentials at equilibrium.

At first sight this seems to make the choice of the mass units an entirely arbitrary one; but I think that this is not the case, and Ostwald has himself shown the way out, apparently without realizing it. The difficulty is in the Gibbs definition of the potential, p. 93. "If to any homogeneous mass we suppose an infinitesimal quantity of any substance to be added, the mass remaining homogeneous and its entropy and volume remaining unchanged, the increase of the energy of the mass divided by the quantity of the substance added is the *potential* for that substance in the mass considered."

This definition is absolutely right; but, as Ostwald¹ has pointed out, we cannot determine the absolute value of the chemical potential of any substance because we do not know the change of the energy with the change of mass. All we can do is to measure differences of chemical potential. As I see it, this means that we are always measuring the chemical potential of a reaction and that consequently we must use the mass units of the reaction. If we are making electrometric measurements the unit is the mass associated with the unit quantity of electricity, the coulomb in electrochemical work. If we are studying pressure relations in a gas or a solution, the unit is the molecular weight of the substance or the ion as the case may be.

I have thought that the electromotive force was a measure of the chemical potential of the system and that there should be a chemical potential for any organic compound if we could only measure it. It is now clear that this was a mistaken point of view. Since we measure only the difference of chemical potential for a given reaction, there are really as many chemical potentials in an organic compound as there are bonds which can be broken. It is these values which must be measured some day.

Another reason for writing this article is that we do not yet make the use of the chemical potential in chemistry that I am sure we ought to make. It seems probable that this is due in part to our misconceptions of the chemical potential. Gibbs deduced the phase rule from the relation among the potentials, and Lash Miller has made use of it to a limited extent in discussing changes of solubility, and it is recognized that electromotive force determinations measure differences of chemical potential; but that is about as far as we go.

Guldberg and Waage deduced the mass law from assumptions in regard to reaction velocity and Gibbs deduced the mass law from the relation between the potentials at equilibrium; but no one, so far as I know, has ever deduced the reaction velocity formulas from the chemical potentials, though Nernst has suggested that the reaction velocity may be proportional to the difference of chemical potential divided by the unknown chemical resistance. Of course one can substitute from one set of equations to the other. If we consider the reacting substances as present in equivalent quantities, we can write for monomolecular, bimolecular, and trimolecular reactions the equations $d\mu/dt = R$, $d\mu/dt = R(A-x)$ and $d\mu/dt = R(A-x)^2$ respectively; or for the general case $d\mu/dt = k(A-x)^{n-1}$ where n is the order of the reaction; but we cannot deduce these equations and they are not what we want anyhow. By subtraction, one can also write the general equation

$$\frac{dx}{dt} = \epsilon \frac{\mu_1 + \mu_2 \dots \mu_n}{R}, \text{ which is of no value until we can deduce it and}$$

show that this is the necessary formula and that has not yet been done. Consequently, a further study of the chemical potential is essential.

I feel sure also that some day the history of chemistry will be written as showing the development (conscious and unconscious) of the theory of the

¹ Lehrbuch allgem. Chemie, 2 II, 123 (1902).

chemical potentials; but we are certainly a long way from that still. I hope that this article may stimulate somebody better qualified than I am, and that it will thereby bring that day nearer.

The general conclusions of this paper are:—

1. We never measure any absolute chemical potential but only the difference of potential due to some reaction.
2. The chemical potentials may be referred to any mass units; but general relations are brought out more clearly if the mass units appropriate to the reaction used.
3. When we are studying reactions involving the pressures of gases or the osmotic pressures of solutions, the appropriate mass units are the molecular weights of the reacting substances or ions.
4. If one is studying electrochemical reactions, the appropriate mass units are the electrochemical equivalents, the masses which are transferred with one coulomb. These are equal to the equivalent weights divided by the Faraday constant.
5. Nobody has worked out what the appropriate mass units are in the case of electrical endosmose or of frictional electricity.
6. In the case of organic compounds one can have as many chemical potentials as there are bonds which can be broken or activated.
7. The mass law equations have been deduced from the reaction velocity equations and from the relations between the chemical potentials; but apparently nobody has deduced the reaction velocity equations from the relations between the potentials although the difference of chemical potential must be one of the factors determining the reaction velocity, and in spite of the fact that Ohm's law holds absolutely for reactions taking place under certain clearly-defined conditions.
8. The history of chemistry will undoubtedly be written some day as a study of the conscious and unconscious development of the theory of the chemical potential.

Cornell University.

ON THE SOLUBILITY OF PURE AND ATMOSPHERIC NITROGEN IN DISTILLED AND SEA WATER

BY J. H. COSTE

The solubility of nitrogen in pure water has been investigated by several workers whose results are not very concordant. The case of sea water with its varying salt content has been studied by some of these workers with still less satisfactory agreement.

A very useful critical survey of then available data was made in 1886 by Hamberg¹ who wrote

“Da ich während der Expedition des Freih. von Nordenskiöld, 1883, ein kleines Material von Bestimmungen des Stickstoffgases in Meerwasser gesammelt hatte, musste ich zu deren Verwerthung einige Normalbestimmungen haben um sie damit zu vergleichen. Je mehr ich in die Kritik von Bunsen's, Dittmar's und Tornoë's Bestimmungen hineinkam, desto mehr wurde ich überzeugt, dass diese ganze Frage einer Revision bedürfe. Unter anderem hielt ich es für nothwendig, nicht nur die Wirkung der Temperatur, sondern auch die des Salzgehaltes auf die Menge des Stickstoffgases zu untersuchen.”

Notwithstanding the considerable amount of work which has been done since 1886 those who need exact data will, like Hamberg, conclude that the whole question needs revision. In the following I have tried to discuss and collate the data available .

The Effect of Argon on the Solubility of Atmospheric Nitrogen

The complication introduced by argon in absorptiometric determinations of the solubility of nitrogen seem first to have been realised by C. J. Fox² who, in 1907, discussed the question and deduced an expression for evaluating the error due to the greater solubility of argon than nitrogen. Bohr and Bock³ and Winkler⁴ in 1891 were unaware of the existence of argon, which was discovered in 1894. Winkler,⁵ in 1901, referred to his work as being on atmospheric nitrogen and in a foot-note said “Unter atmosphärischem Stickstoff soll der, aus Luft dargestellte, Argon u. s. w. haltige Stickstoff verstanden werden.” He does not seem to have realised that an error was thereby introduced into his results. The error is peculiar to the absorptiometric method in which a finite volume of water is agitated with a small, finite volume of gas. The

⁵ L. W. Winkler: Ber., **34**, 1408 (1901).

presence in the gas of two constituents of varying solubilities leads to the final equilibrium being obtained between water and a gas containing less of the more soluble than the original mixture. Two definite values may be desired, either the solubility of atmospheric nitrogen α' or that of pure nitrogen α_N . What is actually found in the absorptiometric experiment is something between the two, α . Of these three values, α' is the highest.

Fox gives an expression for the value of $\alpha' - \alpha$ in any absorptiometric experiment in which the composition of the gas experimented with, and the ratio of volumes of gas to water = k are known. Substituting the proper numerical values and using α_A at $0^\circ = 0.0578$ and α_N at $0^\circ = 0.0230$ (Fox) we get

$$\alpha' - \alpha = 0.00001418/k + 0.0582$$

k = volume of residual gas/volume of liquid. A few values of 1000 ($\alpha' - \alpha$) which will be the correction in millilitres of gas for a litre of liquid are given below.

$k = 0$.1	.2	.5	1.0	10
1000 ($\alpha' - \alpha$) = 0.1243	0.09	0.05	0.02	0.01	0.001
Percentage error 1.06	0.39	0.22	0.09	0.04	0.004

In actual working the error would never reach the maximum value nor fall as low as the lowest given, since one could not use an experiment in which all the gas was absorbed nor measure with sufficient accuracy a volume of gas many times that of the liquid. It will be noted however that in the method of working by saturation of the liquid with an unlimited volume of gas and boiling off or pumping out the gas $\alpha' - \alpha = 0$ that is the true absorption coefficient of the gaseous mixture is obtained. What, however, is the absorption coefficient of the pure gas, nitrogen = N_2 ?

Fox shows, and indeed it is obvious, that

$$\alpha_N = \alpha' - 0.01185\alpha_A/0.098815$$

[0.01185 and 0.98815 being respectively the volumes of argon and nitrogen in one volume of atmospheric nitrogen]. Since α_A = about 2.45α and α'/α_N we can simplify this to

$$\alpha_N = 0.9827 \alpha'$$

with an error of not more than, say, $1/1000$. We see therefore that the error, due to argon of an absorptiometric experiment cannot exceed 1% of the value determined and that the difference between the true values for N_2 and atmospheric nitrogen is about 100 ($1 - .9827$) or say 1.7 percent within a wide range of temperature. We can now consider actual results.

Atmospheric Nitrogen in Distilled Water

Table I shows the results obtained by various workers from Bunsen down to Fox.

TABLE I

One litre of distilled water absorbs from atmospheric nitrogen at a pressure of 760 mm + tension of aqueous vapour millilitres of the mixed gas according to

At a temperature of °C	Bunsen	Dittmar	Hamberg	Bohr and Bock	Winkler	Fox
0	20.35	24.40	24.21	(23.88)	23.54	23.59
+5	17.94	21.62	21.42	(21.53)	20.86	21.03
10	16.07	19.43	19.15	(19.56)	18.61	18.95
15	14.78	17.65	17.37	(17.86)	16.85	17.31
20	14.03	16.18	15.98	(16.39)	15.45	15.98
25	—	14.95	14.94	(15.04)	14.34	14.89

Bunsen's¹ results are clearly inaccurate. As I wrote in 1918 his "work stands alone as that of a pioneer and cannot be criticized like that of other workers."²

Dittmar³ was a careful worker but I am inclined to think that there were too many unprotected rubber joints in his apparatus. Most of his results are distinctly higher than those of the others. Hamberg saturated water with air and used a very good gas-extraction and gas-measuring apparatus. He considered air to contain 79.05% of the mixture he called nitrogen. Neither his results or Dittmar's are affected by error due to argon since in a bubbling process of saturation k is very large. Bohr and Bock used both absorptiometric and boiling-out methods but their results are not easily amenable to correction. Winkler's absorptiometric results given in Table I are not those he published but are corrected for the value of k which was fairly constant at $1/4$. The figures are taken from Landolt and Börnstein, Fifth edition, p. 765, Table 131b (1923). I have satisfied myself that the corrections are of the order required by Fox's expression. Fox's values are those given in Landolt and Börnstein and calculated from his values for the "nitrogen" in air. It will be seen that above 5° Hamberg and Fox agree well and the following rounded figures are probably fairly trustworthy.

One litre of	10°	15°	20°	25°C
water at				
dissolves	19.0	17.3	16.0	14.9ml.
	of atmospheric nitrogen.			

The disagreement between various workers at the lower temperatures is very remarkable. I note that the only tables given now in Landolt and Börnstein are Winkler's and Fox's, recalculated as above mentioned.

¹ R. Bunsen: "Gasometry" (Trans. H. Roscoe, 1857).

² J. H. Coste: J. Soc. Chem. Ind., 36, 846 (1917). The "Absorption of Atmospheric Gases by Water."

³ W. Dittmar: "The Challenger Expedition, Report on Chemistry and Physics."

Pure Nitrogen in Distilled Water

The only persons who appear to have determined directly the solubility of N_2 in water are Braun¹ and Adeney and Becker.² Adeney and the late H. G. Becker published a few values incidentally in one of their papers on the rates of absorption. All the other workers used "nitrogen" from air and heated copper or air and phosphorus all but Fox and Winkler, believing this to be nitrogen. Fox corrected in some way to pure nitrogen but his results given on p. 73 of his paper (Faraday Society edition) do not agree with his correct formula for obtaining α_N already mentioned.

In Table II Fox's results for atmospheric nitrogen calculated to α_N by his formula are taken from Landolt and Börnstein. They differ from his published figures as will be seen; but those I have recalculated are certainly correctly reduced. Winkler's results are from the same source and Hamberg's figures have been multiplied by 0.9827.

TABLE II

One litre of distilled water absorbs from N_2 at a pressure of 760 mm + tension of aqueous vapour millilitres of the gas.

According to	At 0°	5°	10°	15°	20°	25°
Hamberg	23.79	21.05	18.81	17.03	15.70	14.68
Winkler (L and B)	23.12	20.50	18.29	16.56	15.18	14.10
Fox (L and B)	23.19	20.68	18.63	17.02	15.72	14.65
Fox (paper)	23.00	20.64	18.54	16.84	15.54	14.43
Braun		21.73	20.03	17.89	16.21	14.32
Adeney and Becker		20.80	18.60	17.01	15.60	14.45

I have graphically interpolated Adeney and Becker's values which it will be seen agree well with Fox's and Hamberg's. Braun's results agree with those of no other worker.

We now come to the case of greatest practical interest, that of

Atmospheric Nitrogen in Sea Water

Only four workers appear to have interested themselves in this matter and of these two, Dittmar and Tornøe left only the most casual record of the salt content of the water they used. Tornøe said he used a sea water of somewhat high density whilst Dittmar's artificial sea water was prepared" so as to represent about an average Challenger water." Hamberg, commenting on this uncertainty, informs us that he himself used waters of 1.7784%, 2.6580% and 3.5126% content of total salts whilst Fox used made up sea water containing about 7.5, 15.20 and 23 per mille Cl'. Hamberg used the following expressions

¹ L. Braun: Z. physik Chem., 33, 721 (1900). "Über die Absorption von Stickstoff und von Wasserstoff in wässrigen Lösungen verschieden dissociierter Stoffe."

² W. E. Adeney and H. G. Becker: Proc. Roy. Dublin Soc. (2) 15, 44, 609 (1919). "The Determination of the Rate of absorption of Atmospheric Nitrogen and Oxygen by Water."

Water of salt content	Absorbs at 760 mm dry air pressure and the temperature to form atmospheric air the quantity of nitrogen in ccs.
0.0%	$19.139 - 0.48616 t + 0.009307 t^2 - 0.000006353 t^3$
1.0%	$17.712 - 0.42828 t + 0.0078736 t^2 - 0.000005362 t^3$
2.0%	$16.446 - 0.38260 t + 0.0068794 t^2 - 0.000004698 t^3$
3.0%	$15.342 - 0.34922 t + 0.0063180 t^2 - 0.000004360 t^3$
3.5%	$14.851 - 0.33720 t + 0.006200 t^2 - 0.000004313 t^3$

and gave a table for the nitrogen content of water of these salinities for each degree of temperature from -3° to $+25^{\circ}$. Fox used the following expression in calculating a table for atmospheric nitrogen at a dry pressure of 760 mm for each 4° from 0° to 28° and for each 4 parts of Cl' per thousand from 0 to

$$1000\alpha = 18.639 - 0.4304 t + 0.007453 t^2 - 0.0000549 t^3 \\ - \text{Cl}' (0.2172 - 0.007187 t + 0.0000952 t^2)$$

In order to compare the results of these two workers I have calculated from Knudsen's relationship—total salt content = 1.805 Cl' + 0.03 the Cl' content corresponding to the salt contents for which Hamberg has given values and used Fox's correcting term for Cl' for the 4° intervals selected by this worker. The results are given in Table III.

TABLE III

Number of millilitres of atmospheric nitrogen absorbed from air at a pressure of 760 mm + tension of aqueous vapour by water of the salinity or chlorions content indicated at temperatures between 0° and 24° .

S°/∞	Cl'°/∞	0°	4°	8°	12°	16°	20°	24°
0.00	H	19.14	17.34	15.81	14.53	13.48	12.63	11.95
	F	0.00	18.64	17.02	15.63	14.45	13.45	12.59
10.00	H	17.71	16.12	14.76	13.61	12.66	11.87	11.23
	F	5.52	17.44	15.97	14.71	13.56	12.75	11.97
20.00	H	16.45	15.02	13.80	12.76	11.89	11.17	10.58
	F	11.06	16.24	14.92	13.80	12.85	12.05	11.36
30.00	H	14.34	14.04	12.93	11.99	11.19	10.54	10.00
	F	16.63	15.03	13.86	12.87	12.04	11.35	10.73
35.00	H	14.85	13.60	12.43	11.62	10.87	10.25	9.73
	F	19.37	14.43	13.34	12.42	11.65	11.00	10.43

H = Hamberg's values.

S °/∞ = Total salts (gms) in 1000 gms.

F = Fox's values.

Cl'°/∞ = Chlorions (gms) in 1000 gms.

It will be seen that the middle parts of the table agree well but that the two sets of figures are rather far apart at temperatures below 8° and for the higher temperatures at the higher salinities. The uncertainty as to saturation is only appreciable above 2% for distilled water and strong sea water at 0° .

On this point it may be recalled that Hamberg commenting on the difference of Tornøe's results from his says. "Für 0° , die Temperatur bei welcher die Unterschiede zwischen Tornøe's, Dittmar's und meinen Resultaten am grössten sind, ist die Zahl, welche ich gefunden habe die Durchschnittszahl von neun einfachen, gut mit einander ueberstimmenden Bestimmungen." This seems to point to the probable accuracy of the higher figure.

In 1923 I published a graph¹ showing the proportions of "nitrogen" and oxygen absorbed from air at a total pressure (air + water vapours) of 760 mm and varying temperature and salinities. In using this, which is based on Fox's values regard should be had to the likelihood that values in the regions just indicated are lower than they should be.

Probable Causes of the Discrepancies between the Results of Different Observers

The differences which have been shown to exist between the results of workers who seem to have used great care are, when all corrections have been made, larger than one would be inclined to expect. I suggest the following causes as contributory.

1. The slowness of exchanges between gas and liquid phases as saturation is approached causes the differences of tension or volume of the gas phase to be so small that the human tendency to consider them insignificant may overcome sound judgment. The accuracy of an absorptionmetric experiment depends in the first place on the absolute freedom of the liquid from the gas or any gas at the beginning, that is, its tension should be exactly that of saturated water vapour, and secondly on the exact measurement of the loss of volume or tension of the gas. In a boiling-out or pumping-out experiment there seems to be no very exact criterion of the end of the exhaustion as aqueous vapour is ever present.

2. The changes in the properties of water towards the freezing point may have some effect: (a) the viscosity increases very rapidly as the water cools and the effect of agitation in mixing the liquid will no doubt be much decreased: (b) it seems probable that the region of maximum density may introduce some anomalies which a careful study would disclose.

3. The real difficulty of freezing water from air by boiling was pointed out by Leduc² in his work on the density of ice. He found it impossible (contrary to Bunsen's statement) to get a clear ice from water which had only been boiled and even after three freezings in vacuo under "huile de vaseline" found some cloudiness. The density of this ice was 0.0004 higher than that from boiled water. Leduc made the following

"Remarque relative à l'analyse des gaz en dissolution dans l'eau.

On voit, par ce qui précède, que l' eau longuement bouillie retiens une quantité de gaz fort appréciable, qu'elle abandonne au moins partiellement en se congelant. . . .

¹ J. H. Coste: 48, 433, (1923) "The Absorption of Atmospheric Gases by Water," Analyst.

² A. Leduc: Compt. rend., 142, 149 (1906). "Sur la densité de la glace."

Il en résulte que l'analyse des gaz de l'eau, telle qu'elle se pratique toujours, est incomplète et par suite inexacte.

Si l'on admet que l'écart entre le nombre de Bunsen et le mien est dû uniquement à ce que ce savant a solidifié complètement de l'eau simplement privée de gaz par ébullition prolongée on arrive à cette conclusion que cette eau renfermait encore près de 1 cm³ de gaz par litre mesuré sous la pression atmosphérique). . . ."

This observation of Leduc's shows that in the absorptiometric method there is some danger of incomplete preliminary removal of the gases of air from water. The result of this would be that less gas would be absorbed in the actual experiment than would have been absorbed by air-free water. A similar error is liable to affect the final extraction of gas in the boiling-out class of methods by reducing the actual volume of gas yielded by the water. It seems unlikely that the error should be as great as Leduc seems, on indirect evidence, to suggest.

The separation of dissolved gases from water when it freezes is one of the troubles of the maker of artificial ice. A clearer and more marketable product is obtained from gas-freed water. R. T. Gunther¹ has also called attention to the beautiful forms assumed by the chains of air bubbles which separate when water in a bottle is allowed to freeze slowly by exposure in frosty weather.

It would appear that the best way of extracting dissolved gases from water is to introduce the water into a vacuum vessel, boil, freeze, evacuate, melt, boil, freeze and again evacuate, repeating the cycle until a clear ice is obtained and no more gas can be collected. The low tension of aqueous vapour at 0° (4.579 mm) would prevent the volatilisation of much water during evacuation.

I hope as the time may allow, to make some determinations of the solubility of nitrogen, using the method of congelation for freezing the water from gas.

Summary

When the proper allowances have been made for the effect of argon on the solubility of atmospheric nitrogen, considerable uncertainty exists as to the absorption coefficients of both this mixed gas and pure nitrogen in distilled water.

A similar uncertainty exists in the case of sea water.

Hamberg's and Fox's results obtained by different methods agree well in most cases. There is some reason for considering Hamberg's results more exact than Fox's at low temperatures (below 8°).

Congelation appears to be the best means of freeing water from dissolved gases.

THE ADSORPTION OF GASES BY METALLIZED SILICA GELS¹

BY L. H. REYERSON AND L. E. SWEARINGEN

The problem of specific adsorption has attracted considerable attention in recent years. The work of Langmuir and Harkins has focused attention upon molecular orientation at surfaces while the work of Taylor and his colleagues at Princeton has been correlating adsorption and catalytic activity. Considerable work has been published on specific adsorption as well as the large amount of work which has appeared on non-specific adsorptions such as adsorptions by charcoals and silica gel. The following investigation was begun with the view of studying specific adsorption by metals using silica gel as the support material and later using the information in catalytic studies.

In the case of the metallized silica gels the adsorption of gases would in general be that of silica gel itself plus any specific adsorption which might be due to the metals which has been deposited as films on the surfaces of the gel itself. This would be true provided the deposition of metal did not appreciably cut down the effective surface for adsorption on the one hand. On the other hand it is barely possible that the deposition of metals might actually increase the total surface available for adsorption. Certain experiments reported in this paper give evidence that the extension of surface plays no important role. The results indicate that specific adsorptions may be superimposed upon non specific adsorptions.

Experimental

The metallized gels used in this investigation were prepared according to the method of Latshaw and Reyerson². After reduction by adsorbed hydrogen the metallized gels were dried at 110° in an atmosphere of hydrogen. In the case of the copper-treated gel it was found necessary to complete the reduction in hydrogen at higher temperatures since the first reduction seldom reduced the cupric ion below the cuprous condition. Adsorptions were measured for silica gel and silica gel metallized with silver, copper, platinum and palladium respectively. Adsorption isotherms were obtained for oxygen, carbon monoxide, carbon dioxide, methane and ethylene upon silverized gel at various temperatures. In the cases of platinized, palladized and copperized gels, the adsorption of hydrogen and sulphur dioxide was also measured. The adsorption measurements were carried out in an apparatus as shown in Fig. 1. Briefly the apparatus consisted of an adsorption bulb, A, connected by glass tubing to a mercury manometer, B, and a water-jacketed gas-measuring burette, C. This system was connected to the evacuating system by glass tubing with a stop cock at E. The gas burette was 50 cc. capacity and it was

¹ The work described in this paper formed part of a thesis submitted to the Graduated Faculty of the University of Minnesota by L. E. Swearingen in partial fulfilment of the requirements for the degree of Doctor of Philosophy, June 1926.

² J. Am. Chem. Soc., 47, 610 (1925).

graduated to tenths of cubic centimeters. Mercury was used as the confining liquid in this burette. A vacuum was produced in the system by a Stimpson double suction mercury vapor pump, supported by a Cenco Hy Vac pump. A McLeod gauge for measuring pressure was sealed directly into the glass mercury pump.

The gases used in the adsorption measurements were obtained and purified in the following manner. The nitrogen used in the early part of the work was prepared by heating a solution of equal parts of sodium nitrite, ammonium sulphate and sodium dichromate. The gas was passed over heated copper turnings to remove any oxygen and then collected and stored over water. Before use the gas was dried by passing it through concentrated sulphuric acid and then through a tube containing phosphorus pentoxide. Later in the work a tank of nitrogen was obtained that analyzed 99.7% nitrogen. This gas was first passed through alkaline pyrogallol and then dried as above before use.

Carbon monoxide was prepared, as needed, by the interaction of sulphuric and formic acids. The sulphuric acid was heated, in a suitable container, on a steam bath and the formic acid was admitted by means of a separatory funnel. The gas was bubbled through a solution of potassium hydroxide and then through concentrated sulphuric acid. It was finally dried over phosphorus pentoxide before use.

The carbon dioxide was obtained from a tank of commercial gas. It was adsorbed more than 99% by a solution of potassium hydroxide. The gas was dried over sulphuric acid and then passed through a tube containing granules of anhydrous calcium chloride.

The oxygen used was taken from a tank of compressed oxygen. It was adsorbed more than 99% by an alkaline solution of pyrogallol. It was dried by bubbling twice through concentrated sulphuric acid.

The hydrogen was obtained from a tank of electrolytic hydrogen. The gas was passed through a solution of alkaline pyrogallol and then through a tube containing some platinized silica gel. This tube of gel was heated to 120° to 130°. It had been previously found that the platinized gel would cause small percentages of oxygen to combine completely with hydrogen at these temperatures. The hydrogen was finally dried over phosphorus pentoxide.

The methane used was obtained from the Carbide and Carbon Chemical Corporation and was taken as needed from a tank of the compressed gas. The gas was washed with water, passed through a solution of alkaline pyrogallol,

FIG. 1

and then dried by bubbling twice through concentrated sulphuric acid. The ethylene was used from a tank of compressed gas which had been prepared commercially for anaesthesia. Analysis showed it to be 97% pure. It was for our purposes washed successively with water, sulphuric acid, and a solution of potassium hydroxide. It was finally dried over sulphuric acid.

The helium which was used to determine the volume of the bulb was obtained through the courtesy of the Bureau of Mines. The sample as obtained contained about 94% of helium. The principal impurity was nitrogen. The impurities were adsorbed by passing the gas through a tube of cocoanut charcoal immersed in liquid air.

The adsorption measurements were made in essentially the following manner. A sample of the gel was first weighed into the adsorption bulb, A, and the bulb sealed to the apparatus. Before making adsorption measurements the entire apparatus was washed with the gas whose adsorption was to be measured. An exception to this procedure was made in the case of carbon monoxide and the platinized gel. The preliminary washing was omitted in this case because the work of Taylor and Burns¹ had shown that the adsorption of carbon monoxide by platinum had been reduced by about 63% following an initial treatment with carbon monoxide. The bulb containing the gel sample was then immersed in an oil bath which was heated to 200°, and the evacuating pumps started. In order to obtain consistent results it was necessary to adopt a uniform procedure. The bulb was heated at 200° for a period of three hours and the vacuum pumps were operated continuously during the entire period. During the process of evacuation the gas burette would be filled with the gas which was to be adsorbed. After remaining in the burette for about two hours, the gas volume, the temperature of the water jacket and the barometric pressure were recorded. By means of the leveling tube, D, a fine adjustment to atmospheric pressure could be obtained in determining the volume of the gas in the burette.

Upon completion of the evacuation process, stop-cock, E, was turned so that the connection to the pumps was broken. The oil bath was removed and the bulb brought to the temperature at which the adsorption was to be measured. Adsorptions were measured at the following temperatures: 0°, 64.5°, 100°, 138° and 218°. At 0° finely cracked ice mixed with water was used in a Dewar flask. Boiling methyl alcohol was used for the temperature of 64.5°, boiling water at 100°, boiling xylene at 138°, and boiling naphthalene at 218°. In each case these liquids were contained in large flasks equipped with reflux condensers and in no case was the adsorption bulb permitted to come in contact with the boiling liquid, but it was bathed in the vapors from the liquid. After the adsorption bulb and contents had reached temperature equilibrium, the manometer was read and gas admitted from the gas burette through the stop-cock at the top of the burette. The gas was added in small quantities, the successive additions being made only after the manometer indicated that equilibrium had been reached. Three successive readings at

¹ J. Am. Chem. Soc., 43, 1273 (1921).

fifteen minute intervals, which showed no change, were taken as indicating the establishment of equilibrium. The total volume of gas added, the temperature and pressure at which the added volume was measured, together with the manometer reading, were all recorded. The extent of adsorption at different pressures could readily be obtained from this data together with a knowledge of the free space in the bulb. Gas volumes were always corrected to standard conditions.

During the early part of the work, nitrogen was used to determine the free space in the bulb. The capacity of each bulb and gel sample was determined prior to the adsorption study and the adsorption of gas was taken as the difference between this volume at the several pressures and the volume of gas admitted at the given pressure, all volumes being changed to standard conditions. Later a comparison was made between the volume of a bulb as determined by nitrogen and the volume as determined by helium. In these cases silica gel was used in the bulb and two separate measurements were carried out. In one case helium was used to fill the bulb and then removed and nitrogen admitted. In the other case the gases were used in the reverse order. No difference in total volumes could be observed with the reversal of the order of admission. The comparative data for a set of measurements are given in Table I.

TABLE I

Comparative Data on the Adsorption of Helium and Nitrogen by Silica gel at 0°

Pressure in millimeters of Mercury	Volume (standard conditions) of gas admitted	Pressure in millimeters of Mercury	Volume (standard conditions) of gas admitted
Helium		Nitrogen	
40.0	1.55 cc	45.0	1.70 cc
92.0	4.00 cc	142.0	5.60 cc
160.5	6.05 cc	238.0	9.15 cc
330.0	13.00 cc	348.0	13.70 cc
540.0	20.40 cc	528.5	21.05 cc
732.8	28.10 cc	745.7	28.90 cc

If the volumes of gas are plotted against pressure it will be found that the adsorptive capacity of the gel for nitrogen and helium is essentially the same for all pressures at 0°. The maximum divergence occurs at a pressure of one atmosphere (extrapolated) and here the difference is less than 0.70 c.c. As a result of this work corrections were made to bring the value of free space to that determined by helium. The adsorption measurements in this investigation were carried out in duplicate.

Results

Table II gives a typical set of adsorption measurements and is experiment 45 in the series.

Figs. 2 and 3 show the adsorption isotherms obtained by plotting amounts adsorbed as ordinates against the pressures as abscissas. From such curves

FIG. 2
Adsorption Isotherms at 0°

FIG. 3
Adsorption Isotherms at 0°

as these the data presented in Table III were obtained. These data give the equilibrium values at 0° . In addition to measurements at 0° , adsorptions of carbon dioxide, ethylene and sulphur dioxide were made at temperatures ranging from 0° up to 218° as indicated previously. Table IV gives the adsorption equilibrium values at actual atmospheric pressures at the time of measurement.

In addition to the forgoing measurements it was thought desirable to study the effect of increasing the metal content on the adsorptive capacity of gels. Accordingly, adsorptions of carbon dioxide, carbon monoxide and ethylene were obtained upon platinized gels Nos. 1, 2, 3, and 4. Platinized

gel 1 contained the platinum from a single reduction, platinum gel 2 contained the platinum from two complete successive reductions by adsorbed hydrogen, No. 3 was subjected to three reductions and No. 4 contained the platinum from four reductions. These measurements were made at 0°. Table V gives the adsorption values for the four platinized gels.

Discussion of Results

To facilitate the comparison of results for the adsorption of the various gases upon the metallized gels, the adsorptions of the gases by the gels at 0° and 760 m.m. pressure has been tabulated in Table VI. The values at 760 m.m. pressure were obtained by extrapolation of the adsorption isotherms from the final equilibrium pressure which was the actual atmospheric pressure observed at the time of measurement.

TABLE VI
Comparative Data on Adsorptions by Different Gels

Gas Adsorbed	Boiling Point (Absolute temperature)	X/M for Silica Gel	X/M for Silverized Gel	X/M for Palladized Gel	X/M for Platinized Gel	X/M for Copperized Gel
H ₂	20.4	0.25	—	0.00	1.10	0.55
CO	81.1	1.60	2.75	2.60	4.60	0.40
O ₂	90.10	0.45	1.35	2.00	2.60	6.40
CH ₄	111.4	1.75	2.20	2.40	2.05	1.40
C ₂ H ₄	169.3	12.70	14.50	26.00	15.10	20.40
CO ₂	194.6	19.40	20.70	32.00	19.60	23.00
SO ₂	263.1	—	—	132.35	102.00	160.00

In the case of silica gel itself the increasing order of adsorption, with the exception of carbon monoxide, follows the increase in the boiling point. In the case of ethylene and carbon dioxide excellent adsorption isotherms were obtained. Little tendency to reach a maximum adsorption was observed in the case of these gases for the range of pressure studied. This is characteristic of nonspecific adsorptions. The adsorption of carbon dioxide is considerably higher than the values obtained by Patrick, Owens and Preston.¹ Above 200 m.m. pressure however, the two isotherms have the same ratio to each other. The difference between these values and those of Patrick, Owen and Preston can be attributed to differences in the water content of the gel and possibly the difference in granule size.

The Freundlich equation for adsorption was found to fit the data whenever there was considerable adsorption. This was also true for the adsorptions on the metallized gels. If the logarithms of the pressures are plotted as abscissas and logarithms of x/m plotted as ordinates, a straight line will result if the values fit the Freundlich equation. This is true for the data here presented.

The adsorption of the gases by the silverized gel show an increase in all cases. The order of adsorption as compared to the boiling points has not changed when compared to silica gel. Per gram of adsorbent ethylene shows the largest increase, 1.80 c.c. more of ethylene being adsorbed by the silverized gel than by the silica gel alone. On the basis of ratio increase however, oxygen and carbon monoxide are more strongly adsorbed by silverized gel than are the other gases. If we assume that the increase for carbon dioxide

¹ J. Am. Chem. Soc., **43**, 1273 (1921).

is due to change in gel structure alone, then on the basis of this ratio increase, the presence of silver in the gel has resulted in the specific adsorption of oxygen, carbon monoxide and possibly ethylene and methane.

The adsorption values for the palladized gel are not strictly comparable to the other adsorptions because the silica gel which was used was from a second preparation of the gel. It shows distinctly greater adsorptive capacity for carbon dioxide. This may be attributed largely to gel structure since Taylor and Burns¹ have shown that palladium adsorbs carbon dioxide but slightly. If we make this assumption then by comparison with the data on the first silica gel the gel containing the palladium should adsorb 2.63 c.c. of carbon monoxide, 0.74 c.c. of oxygen, 2.88 c.c. of methane and 20.90 c.c. of ethylene. We find good agreement between these calculated values and the observed results in the case of carbon monoxide and methane. Oxygen seems to be specifically adsorbed by the palladium and there is not much doubt that ethylene is very strongly adsorbed, since there is an adsorption of more than 5 c.c. above the calculated value. Specific adsorption of ethylene by the palladized gel is further indicated by the shape of the adsorption curve. More ethylene is adsorbed at low pressures than carbon dioxide while the carbon dioxide is more strongly adsorbed near atmospheric pressures. This type of curve is a characteristic of specific adsorptions.

In the case of hydrogen the first experimental work indicated zero adsorption. This might be due to two separate factors. Either the drying in an atmosphere of hydrogen filled the palladized gel with hydrogen and this was not subsequently removed by the heating and evacuation, or the palladium surface had become poisoned as regards hydrogen adsorption. Taylor and Burns² have shown that palladium exhibits considerable reluctance in giving up hydrogen so that the first explanation is plausible. Additional work seems to eliminate this possibility in these experiments. Pollard³ has shown that traces of grease poison platinum as far as adsorption of hydrogen is concerned. Accordingly, additional experiments were carried out using the utmost precaution to keep grease away from the palladized gel. The palladized gel then showed an adsorptive capacity of 0.76 c.c. of hydrogen per gram of metallized gel at 0° and 760 m.m. pressure. A repetition of the adsorption measurements decreased the adsorption to 0.55 c.c. per gram of gel. A second set of experiments was then carried out. The palladized gel was first heated in an atmosphere of nitrogen at 120°-140° for a period of four hours. It was felt that this might partially remove any adsorbed hydrogen. The regular procedure for adsorption study was then carried out. The adsorption determined in this experiment gave a value of 0.87 c.c. per gram of the metallized gel. This is so close to the value previously obtained that no further work was done on this phase of the problem. It would appear from these results that palladium is also very easily poisoned as far as hydrogen adsorption is concerned. An

¹ J. Am. Chem. Soc., 29, 421 (1925).

² J. Am. Chem. Soc., 43, 1273 (1921).

³ J. Phys. Chem., 27, 356 (1923).

adsorption of 0.87 c.c. of hydrogen per gram of palladized gel does not indicate a marked specific adsorption of hydrogen by the palladium present in the gel.

The platinized gel was prepared upon the same silica gel as was used in all of the work except the palladized gels. It is evident from the adsorption values that there is no longer much relation between amounts adsorbed and boiling points of the substances adsorbed. The amount of carbon dioxide adsorbed is the same as for silica gel itself. The presence of platinum in the gel has considerably increased the capacity of the gel to take up ethylene. The adsorption of methane has not greatly increased. However, in the cases of hydrogen, oxygen, and carbon monoxide the platinized gel is able to adsorb from three to five times as much gas as the silica gel. The marked adsorption of carbon monoxide fits well with the experiments of Pollard and the adsorption of hydrogen, oxygen, and carbon monoxide agrees well with the work of Taylor and Burns on platinum black.

The copperized gel shows very different adsorptive capacity when compared to the other adsorbents. There is less carbon monoxide and methane adsorbed than for the unmetallized gel. Hydrogen is about twice as strongly adsorbed while large increases are noted for the other gases. About thirteen times as much oxygen is adsorbed as for the gel itself and this may even mean reaction of the copper film with oxygen. It is evident that the copper in the gel specifically adsorbs oxygen and ethylene and perhaps hydrogen, carbon dioxide and sulphur dioxide.

The effect of temperature upon the adsorption of the gases is the same as expected. Increased temperature rapidly cuts down the adsorption. It should be noted however that the gases which are specifically adsorbed are still slightly adsorbed at a higher temperature than those not specifically adsorbed.

The effect of successive metallizations by platinum does not show any great change except in the case of carbon monoxide where a steady increase in amount adsorbed is noted in going from the singly metallized gel to that metallized four times. This tends to confirm the point of view that carbon monoxide is adsorbed specifically by platinum. In the case of ethylene a lowering of the adsorptive capacity is noted for the case of the gel twice metallized and then there is a slight increase over this value for the gels metallized three and four times. Specific adsorption by the platinum may be overcoming the filling of the capillaries in the gel by the metal.

Summary

1—The adsorption of gases upon silica gels metallized with silver, copper, platinum and palladium has been measured.

2—Hydrogen is adsorbed appreciably more upon the copper, platinum and palladium treated gels.

3—Carbon monoxide is specifically adsorbed by all the metallized gels except copper.

4—Oxygen is very specifically adsorbed by the copperized gel. The other metallized gels also exhibit specific adsorption for oxygen.

5—There appears to be no marked specific adsorption of the gels for methane.

6—The metallized silica gels all adsorb ethylene more strongly than does silica gel.

7—The adsorption of carbon dioxide gives little evidence of a specific effect except perhaps in the case of copper.

A STUDY OF THE MECHANISM OF THE CATALYTIC DECOMPOSITION OF ESTERS BY NICKEL

J. N. PEARCE AND C. N. OTT

The catalytic properties of finely divided nickel recently reduced from its oxide were first noted by Sabatier¹ about 1880. He and his co-workers, and others, have since made a great number of further discoveries of uses for nickel prepared in this way. The most important of these are met with in the hydrogenation of the unsaturated organic compounds. Nickel may also act catalytically as a dehydrogenating or as a decomposing agent under proper conditions, as in the decomposition of olefines and the aliphatic amines.

Sabatier and Mailhe² have shown that aliphatic acids over freshly reduced nickel break up in two ways. The first consists of the elimination of CO₂ from one molecule of acid; the second, the elimination of water and CO₂ from two molecules of acid, thus

Sabatier and Senderens³ state that ketones tend to decompose with the elimination of CO,

The groups, R-, combine to some extent, but chiefly decompose to form lower hydrocarbons, hydrogen and carbon. Acetone, for example, is decomposed slowly by nickel⁴ at 240°, and rapidly at 270°, yielding CO and the CH₃-radicals. The latter combine to give a little ethane; by further decomposition they yield also C₂H₄ and H₂, but the chief products formed were found to be CH₄, H₂ and C.

Nickel acts energetically on the alcohols.^{3,4} Methyl alcohol begins to decompose at temperatures as low as 180°, two thirds of the aldehyde formed being destroyed. The reaction proceeds very rapidly at 250°, where eight ninths of the aldehyde is destroyed and the gaseous mixture contains forty five percent of H₂ along with CH₄ and CO. At 350° there is no longer any aldehyde and no carbon monoxide: the gas is a mixture of CH₄ and CO₂. Ethyl alcohol³ is rapidly decomposed by nickel above 230° to give acetaldehyde and hydrogen; above 330° the aldehyde is completely decomposed into methane and CO, thus,

Similar results are obtained with propyl alcohol; seventy five percent of the aldehyde formed is decomposed at 260° by a two step process into first propyl

aldehyde and hydrogen, after which the aldehyde breaks down to form C_2H_6 and CO. When alcohol vapors are passed over nickel at high temperatures we not only have the dehydrogenation to the aldehyde, but also there is possible a second side reaction which takes place with measurable velocity. In this case there is a dehydration of the alcohol to form an unsaturated hydrocarbon:

This reaction is inserted because it may account in part for some of the traces of unsaturated hydrocarbons found in this work.

Sabatier and Senderens³ have found that the aldehydes are decomposed more readily than are the ketones when passed over nickel. Reduced nickel acts energetically at temperatures above 200° . Formaldehyde is decomposed to H_2 and CO. The higher aldehydes break down into CO and the next lower hydrocarbon.

Ethyl ether¹ is readily hydrogenated by nickel giving methane, a little ethane and carbon monoxide; the latter is further reduced to methane at higher temperatures. The extent of this reduction is dependent largely upon the temperature, the nature of the possible reduction products being indicated by the following reactions:

Bancroft² states that if ether is passed over pulverulent nickel, the dissociation will probably be to $C_2H_5O + C_2H_6$, or to $C_2H_5O + C_2H_4 + H$. In the first case the final products will be $2C_2H_4$ and H_2O just as with alumina. In the second case they are likely to be $CH_3CHO + C_2H_4 + H_2$, though the ethylene and hydrogen may combine more or less completely to form ethane.

In the absence of catalysts formic esters are found to be quite stable. No appreciable decomposition is observed when ethyl formate is passed through a glass tube at 400° , but the decomposition is very rapid when the ether is in contact with catalysts that decompose formic acid. Furthermore, the decomposition takes place at temperatures which are lower than those required for the esters of other aliphatic acids, but higher than those required for formic acid. Sabatier and Mailhe³ have shown that this decomposition takes place according to two different reactions at the same time, the one similar to the usual decomposition of esters of other aliphatic acids:

The whole or part of the alcohol formed is dissociated at the reaction temperature into hydrogen and aldehyde, the aldehyde in turn being unstable dissociates into CO and a hydrocarbon. Formic esters are easily decomposed by nickel above 220° .

The direct hydrogenation of carbon monoxide over nickel¹ begins at around 180°-200° and goes on rapidly without complications at 230°-250°. With the theoretical mixture of hydrogen and carbon monoxide, 3:1, the reaction is practically complete, the resulting gas being nearly pure methane. The reaction is always less complete when the carbon monoxide is in excess. If the operation is carried out at temperatures above 230° complications arise due to the decarbonization of the carbon monoxide which is accelerated by the nickel.

The decomposition increases with rise in temperature and is complete at 350°, if the flow of gas over the catalyst is sufficiently slow. The carbon dioxide which is thus formed is partially hydrogenated. Its proportion is greater, the higher the temperature, since the secondary reaction which produces it is greatly accelerated by rise of temperature. Thus, when operating at 380° with the theoretical mixture which gives methane completely at 250°, a gas is obtained which contains by volume: CO₂, 10%, CH₄, 67.9%, H₂, 21.6%. When the percentage of carbon monoxide is sufficiently increased, the hydrogenation is greatly weakened; much hydrogen passes through and the proportion of carbon dioxide becomes very large.²

Like carbon monoxide, carbon dioxide is readily hydrogenated over nickel to form methane:

The reaction begins at a higher temperature than with carbon monoxide, about 230°, and is rapid above 300°. With sufficient excess of hydrogen the carbon dioxide disappears almost completely.

Theoretically the decomposition of esters by nickel might take place in one or more of several different ways. Ethyl acetate, for example, might decompose to form the CH₃- and the -COOC₂H₅ radicals which in the presence of hydrogen should form, respectively, methane and ethyl formate, or the ultimate reduction products of the latter, namely, methane and carbon monoxide:

The ester might break down to form the ethyl and acetate radicals, which with hydrogen would give ethane and acetic acid, or its decomposition products:

Further, the ester might decompose more completely to form carbon dioxide, the methyl and ethyl radicals, or possibly carbon dioxide and some propane. In the former case we should expect to obtain methane, ethane and perhaps the reduction products of carbon dioxide, if hydrogen were present.

¹ Sabatier and Senderens: Bull., (3) 29, 294 (1908).

² Sabatier and Senderens: Compt. rend., 134, 514 (1902).

Finally, as in the case of the aliphatic acids, it is possible for two molecules of the ester to decompose simultaneously into carbon dioxide, acetone and ethyl ether, thus,

As previously mentioned,² the acetone may then break down to give methane, carbon monoxide, hydrogen, carbon, and some ethane and ethylene, while the ether⁵ in the presence of hydrogen would be reduced to methane, ethane and carbon monoxide. As is evident, it is possible to apply similarly the various decomposition schemes just mentioned to other esters.

Bancroft¹ states that when ethyl acetate is decomposed by being passed over nickel, carbon dioxide and propane are formed. He says that the reaction is probably not complete, but does not state at what temperature this decomposition takes place. He further points out the lack of knowledge of the exact mechanism of the reaction, and suggests that hydrogen be mixed with the ester before it is passed over the nickel so that the decomposition products may be reduced before they have opportunity to react with each other, and may thus be identified.

A study, therefore, of the products formed when an ester is passed over nickel, both in the presence and in the absence of added hydrogen, should throw some light on the mechanism of its decomposition. In a previous paper Pearce and Ott² studied the decomposition of ethyl acetate by nickel at temperatures between 300° and 450°. From the nature of the products obtained they concluded that the initial decomposition is most probably represented by scheme (IV): $2 \text{CH}_3\text{CO}_2\text{C}_2\text{H}_5 \longrightarrow (\text{CH}_3)_2\text{CO} + (\text{C}_2\text{H}_5)_2\text{O} + \text{CO}_2$. The acetone and ether formed were then decomposed to products stable at the temperatures involved. The decomposition products which were actually found are identically the same as those demanded by such a step-wise scheme of decomposition. They also found that the addition of gaseous hydrogen to the ester vapor before passing over the catalyst causes no change in the nature of the products formed. This might have been expected since hydrogen is actually formed in the reaction. It was also found that raising the temperature increases the amount of carbon dioxide and methane in the products, and decreases the amounts of carbon monoxide and hydrogen, probably due to facilitation of the secondary reactions:

In the present work we have extended the study to the decomposition products of methyl and propyl acetates and methyl propionate at various temperatures between 300° and 700°. By this means we hoped to test further the above schemes of decomposition and to determine the effect of different groups upon it.

Materials used

ESTERS. The original samples were washed several times with distilled water, a saturated salt solution being used in the case of methyl acetate. An equal volume of water was then added and the ester distilled off. The distillate was dried over anhydrous potassium carbonate for several days, then over phosphorus pentoxide, and finally fractionated. The following fractions were retained: methyl acetate, 53.2°-53.4° at 745 mm.; ethyl acetate, 76.4°-76.6° at 748 mm.; propyl acetate, 101°-102° at 747 mm.; methyl propionate, 79°-80° at 748 mm.

NICKEL. Approximately equal parts by weight of recrystallized nickel nitrate and coarse pumice, "pea crystal," were heated together in a furnace at 400°-450° for about six hours, or until the evolution of fumes had ceased. The material was allowed to cool and was stored in a desiccator until needed. It was later reduced at the lowest possible temperature in the tube in which it was to be used. When first prepared the nickel is black in color, but after use for some time it becomes brown or gray and is only slowly soluble in dilute hydrochloric acid.

HYDROGEN. The hydrogen was generated by the electrolysis of a concentrated solution of sodium hydroxide. The gas was bubbled through sulphuric acid, then over heated copper gauze and solid sodium hydroxide.

Apparatus

The ester was placed in a 10 c.c. reservoir from which it was forced by pressure through a fine capillary into a vaporizing chamber kept at about 20° above the boiling point of the ester. The vapors passed directly into the catalyst tube which was of pyrex glass, 90 cm. long and 10 mm. internal diameter. The tube was placed in a 75 cm. electric furnace which could be used for temperatures up to 800°. The temperature of the gases was taken just as they left the catalyst by means of a calibrated copper-constantan thermocouple and are accurate to $\pm 1.00^\circ$. The liquid portion of the products was condensed in an ice bath and the gases were collected over dilute sulphuric acid which had been previously saturated with the gases.

The gases were analyzed by means of a modified Orsat apparatus. The carbon dioxide was determined by absorption in a concentrated potassium hydroxide solution, unsaturated hydrocarbons by concentrated sulphuric acid, oxygen by alkaline pyrogallate, and carbon monoxide by acid cuprous chloride. The hydrogen and hydrocarbons were determined by fractional combustion over heated copper oxide in a quartz tube, according to the method prescribed by White.¹ The gas burette was water-jacketed and was fitted with a manometer and a pressure compensating tube.

Experimental Method

The tube of nickel oxide was placed in the furnace and the heat and hydrogen turned on, thus allowing the reduction to take place at the lowest possible temperature. After five or six hours, when the furnace had reached the de-

¹ White: "Technical Gas and Fuel Analysis," 54 (1913).

sired temperature and the nickel was fully reduced, as evidenced by no further formation of water vapor, the hydrogen was shut off and the vapor of the ester was admitted. In all cases the vapor of the ester was allowed to flow through the catalyst for at least an hour in order that all of the residual hydrogen might be displaced before the samples of the effluent gases were taken for analysis. The products were led through an ice trap where the liquefiable portion was condensed. The gaseous products were collected over dilute sulphuric acid and later analyzed. When it was desired to test the effect of added hydrogen on the decomposition products, the hydrogen was led into the vaporizing chamber where it mixed with the ester vapor before passing over the nickel, and samples of the decomposition products were taken and analyzed as before. The decomposition products from each ester were studied at several different temperatures from 300° up to 700° where sintering of the catalyst probably begins.¹ The experiments at each temperature were checked with new samples of the catalyst. In some instances second runs were made with the same catalyst to determine the influence of the age of the catalyst on the nature and the amounts of the decomposition products.

Analysis of Products

The liquid which was condensed in the ice trap at 0° was analyzed in two ways. Several different samples were fractionated through a 10-inch distilling column and in no case did the corrected boiling points differ by more than 0.2° from that of the original ester. Several samples collected at each temperature were quickly titrated at 0° with N/20 normal sodium hydroxide; these showed no measurable quantity of free acid. The purity of the condensed ester was further confirmed by density determinations at 25°.

After the removal of the carbon dioxide, unsaturated hydrocarbons and carbon monoxide, the remainder of the gas was passed over copper oxide at 240°. The contraction following this combustion is equivalent to the volume of the hydrogen in the gas mixture, since the change in the volume of the copper oxide and the volume of the liquid water formed are negligible; the contraction from the subsequent passage of the residue over potassium hydroxide solution would be due to hydrocarbons higher than propane, but none were even found. The remaining gases were passed over copper oxide at 300°. At this temperature propane is burned, and one-half of the increase in volume following this combustion should be considered equal to the volume of propane. To determine the ethane present the residual gases were next passed over copper oxide at 380°, or above; the increase in volume following this combustion is equal to the volume of ethane originally present. The remainder of the gas was considered as methane which burns over copper oxide only when heated to redness. No attempt was made to determine the amount of water vapor formed during the decomposition of the esters; it was condensed along with the undecomposed ester in the trap at 0°.

¹ Smith: J. Chem. Soc., 123, 2088 (1923).

Experimental Results

The experimental results are recorded in Tables I-IV. The experimental temperatures are given in the top horizontal row; the vertical columns contain the percentages of the constituents indicated at the left. The first four columns in each table are obtained from the analysis of the decomposition products of the ester alone. The fifth column shows the effect of the previous addition of hydrogen to the ester before passing it over the catalyst. In the sixth column, when given, are collected the corresponding data obtained by means of a sample of catalyst which had been used for some time previously at the same temperature. Each value given is the mean of at least two independent determinations, differing usually by not more than one percent.

At a few temperatures the volume proportions of the gaseous products fail to approximate 100 by as much as two or three percent. These deviations are not considered important since we are chiefly concerned with the relative proportions of the gases in the mixture.

A comparison of the data obtained for the four esters gives a really dependable basis for deciding upon the mechanism of the decomposition of esters by nickel. It has shown also that the conclusions drawn in the previous paper¹ do not fully represent the exact mode of decomposition. It is obvious that the ester molecule will be weaker at certain points than at others. It is at the weakest point, therefore, that the rupture of the molecule will first occur and in greatest measure when it is subjected to an elevation of temperature. This does not exclude the possible occurrence of other modes of decomposition at the same time, but these will occur in lesser and different degrees depending upon the conditions of stress imposed by the temperature.

The discussion which follows is based upon the single assumption that the initial break in the molecule will occur at the weakest point, and that this point is the same for all esters of the type studied. Again let us consider ethyl acetate as our model. If it decomposes according to Scheme I, methane and ethyl formate, or the decomposition products of the latter, should be formed in the presence of hydrogen. If it breaks up according to II, the hydrogen should cause the formation of ethane and acetic acid. The latter on decomposing should give methane and carbon dioxide. If (III) is the proper scheme, the ester alone should form carbon dioxide and propane; in the presence of hydrogen there should be formed methane, ethane and carbon dioxide. It will be noted that these three schemes call for a change in the nature of the decomposition products in the presence of hydrogen. According to (IV) the ester alone should give acetone, ether and carbon dioxide, the ultimate products being carbon monoxide, carbon dioxide, hydrogen, methane, and small amounts of ethane, ethylene and carbon. Since free hydrogen is already present in the products, the addition of more molecular hydrogen should not greatly alter either the nature or the proportions of the products.

¹ Pearce and Ott: J. Phys. Chem., **28**, 1201 (1924).

Only in scheme (IV) does hydrogen appear, and then only as the product of a secondary reaction, yet even at the lower temperatures hydrogen is present in greater proportion than are any of the other gaseous products. If we consider the products formed when alcohols, aldehydes, ethers, ketones, etc., are passed over nickel, we find that hydrogen is formed only in the dehydrogenation of alcohols, the second product being the aldehyde. Formaldehyde is the exception in that it decomposes at the temperature of the reaction completely into hydrogen and carbon monoxide. There is a second source of hydrogen, namely, that formed in the decomposition of the nascent $\text{CH}_3\cdot$ radical, but the amount produced in this way must be small since the other products resulting from this decomposition, carbon and ethylene, are formed only in negligible quantity.

There is sufficient experimental evidence to show that, in the decomposition of esters by nickel, methane may be formed in at least three ways. Methane is formed by the direct combination of hydrogen with the $\text{CH}_3\cdot$ radical set free at the instant when the ester decomposes thus,

The second product is ethyl formate. It is also formed in the decomposition of ethyl aldehyde (5), and, finally, it is produced by the complete reduction of the two oxides of carbon. A fourth source will be mentioned later.

A study of the reactions show three possible sources of carbon monoxide. They are the decomposition of aldehydes to give carbon monoxide and a hydrocarbon; the decomposition of a formate giving carbon monoxide and an alcohol, which in turn breaks up to form more carbon monoxide and a hydrocarbon; and the decomposition of acetone, yielding carbon monoxide and the two radicals, $\text{CH}_3\cdot$. The last of these must be excluded for reasons which will be explained shortly.

Carbon dioxide has purposely been left to the last because it appears to be the key to the solution of the problem of the mechanism of ester decomposition. Carbon dioxide can form only as a result of the decomposition of carbon monoxide (12), from the decomposition of two moles of acid, (10) and (11), or from the primary decomposition of two moles of ester (IV). In either of the last two cases the amount of carbon dioxide formed should be equivalent to one-half of the number of moles of the acid or ester decomposed. If, on the other hand, one mole of acid decomposes according to (1), or one mole of ester according to (III), then the amount of carbon dioxide formed should be equivalent to the acid or ester decomposed. Whether the carbon dioxide comes from the acid or the ester the quantity should be large. We actually find, however, at the lowest temperatures that the volume of carbon dioxide is relatively small, and that carbon monoxide, which is not even indicated in the initial reaction schemes, is present in relatively large proportions. The fact that for the temperature range studied the percentage of carbon dioxide increases, while that of carbon monoxide decreases with rise in temperature can only lead to one conclusion, namely, that at some low temperature only carbon monoxide is formed. On the basis of these considerations for carbon

dioxide we can, therefore, exclude the possibility of the initial decomposition being represented by schemes (II), (III) and (IV).

There remains then just one plausible guess as to where the molecule first breaks when the ester is passed over nickel. It is that represented by scheme (I). Let us first consider in a general way the decomposition of the esters of acetic acid. The first original splitting common to the molecules of all such esters can be represented by the general reaction:

This is followed immediately by a second reaction in which these radicals are reduced to methane and the formic ester,

Some of the methyl radicals may also combine to form ethane as will be discussed later. The formate at the temperature of the reaction decomposes to form carbon monoxide and an alcohol:

The alcohol in turn decomposes to give hydrogen and the corresponding aldehyde:

The final step in the decomposition consists in the breaking down of the aldehyde molecule to form the next lower hydrocarbon and carbon monoxide.

It is obvious that these successive reactions cannot proceed without the presence of at least an initial trace of hydrogen. Once molecules of the alcohols have been formed, the nascent hydrogen resulting from their decomposition is sufficient to reduce all nascent CH_3- and $-\text{CO}_2\text{R}$ radicals which are subsequently formed. It should be noted at this point also that while one hydrogen atom is required to reduce a $-\text{CO}_2\text{R}$ radical to the formic ester, the alcohol resulting from this produces on decomposition two hydrogen atoms. Thus, the amount of free hydrogen in the gas mixture increases as the total reaction proceeds. Naturally, the question as to the source of the hydrogen necessary to reduce the first CH_3- and $-\text{CO}_2\text{R}$ radicals formed now arises. The stability of the individual paraffin hydrocarbons toward heat varies with their position in the homologous series. It is a well known fact that the higher hydrocarbons will on heating, and especially in the presence of a catalyst, "crack" to form simpler hydrocarbons. The stability of the paraffins increases as the complexity of the molecule becomes less. This is also exactly the order of their ease of oxidation by copper oxide.¹ Methane splits up for the most part into its elements on being led through a red-hot tube, and there is formed at the same time ethane, ethylene, acetylene, and some aromatic compounds, the proportions depending on the temperature. Ethane, ethylene and acetylene behave similarly. In the presence of the proper catalyst this kind of decomposition should take place at a much lower temperature. The free nascent CH_3- radicals are likewise unstable. Two of them

¹ White: "Technical Gas and Fuel Analysis," 54 (1913).

may combine to form an ethane molecule, but some will decompose completely to form free hydrogen and carbon, or partially to form hydrogen and unsaturated molecules. The hydrogen thus formed from the free $\text{CH}_3\cdot$ radicals is most probably that which reduces the radicals formed when the first ester molecules split. The fact that we obtain only traces of free carbon, and at most temperatures either none or only traces of unsaturated hydrocarbons indicates that relatively few of the methyl radicals are thus decomposed. They have either combined with each other to form ethane, or with hydrogen to form methane. Since at a given temperature methane is more stable than ethane, we should expect the tendency to form methane in the presence of hydrogen, $(\text{CH}_3 + \text{H}) \rightarrow \text{CH}_4$, will be greater than the tendency to form ethane, $(\text{CH}_3 + \text{CH}_3) \rightarrow \text{C}_2\text{H}_6$. This is especially true for ethyl acetate at 300° . Bancroft¹ states that heated nickel decomposes ethyl acetate to carbon dioxide and propane, but he gives no reference for the statement. We have found no evidence of propane formation.

Except in the case of propyl acetate, ethylene or other unsaturated hydrocarbons, appear only in minute quantity and then only at the lower temperatures. This would indicate that the unsaturated compounds are not formed at all, or that they are completely hydrogenated by the nickel to methane and ethane. At the higher temperatures they are not stable.

Ethyl propionate is the only ester of an acid higher than acetic acid studied. If the first split of the ester molecule is represented by, $\text{C}_2\text{H}_5\text{CO}_2\text{CH}_3 \rightarrow \text{C}_2\text{H}_5 + \cdot\text{CO}_2\text{CH}_3$, we might expect some butane to be formed, but none was found. Ethane should be more stable than butane at any temperature, and with hydrogen present we should expect, therefore, the formation of a considerable amount of ethane even at the lowest temperature employed, namely, 420° . Since ethane,² and very probably also the $\text{C}_2\text{H}_5\cdot$ radical, decomposes slowly above 325° to give carbon, methane, and free hydrogen, the actual amount of ethane formed will be somewhat less than the reaction equation demands; the amount of ethane produced should and does, decrease with rise in temperature. These deductions are fully confirmed by the experimental data.

Let us now turn to the consideration of the decomposition of the formic esters which are formed when the ester molecule first decomposes. The methyl formate decomposes successively according to the following reactions:

It is evident, therefore, that the complete decomposition of methyl acetate should give relatively small amounts of methane and ethane, and relatively large amounts of free hydrogen and carbon monoxide. Moreover, if the decomposition temperature is sufficiently low, no carbon dioxide should be formed. With rise in temperature carbon monoxide disappears in the formation of carbon dioxide; it is also reduced by hydrogen to form methane and

¹ Sabatier-Reid: "Catalysis in Organic Chemistry," 180 (1922).

² Sabatier-Reid: "Catalysis in Organic Chemistry," 911 (1922).

water. The maximum amount of carbon dioxide is never obtainable at any temperature, because it also is capable of reduction by the free hydrogen present.

Similar successive reactions could be written expressing the decomposition of the ethyl and propyl formates produced in the initial decomposition of the ethyl and propyl acetates. In each case the corresponding alcohol is first obtained. The ethyl alcohol is dehydrogenated to the aldehyde and free hydrogen. The acetaldehyde in turn yields carbon monoxide and methane. This methane together with that formed in the initial splitting of the ester molecule accounts for the large proportion of methane from ethyl acetate. From propyl acetate we should obtain ultimately ethane, hydrogen and carbon monoxide. Propyl acetate should give, therefore, and actually does give, a larger proportion of ethane than do any of the other acetic esters. Since hydrocarbons are formed from all aldehydes, except formaldehyde, the proportion of hydrogen in the effluent gases should be less than that from methyl acetate. The number of equivalents of carbon monoxide possible should be the same for all esters, if none of it is subsequently removed.

Again, we may state that no propane formation has been observed. According to the above considerations we should expect to obtain *n*-propane in quantity only when we decompose *n*-butyl acetate; *n*-butane from *n*-amyl acetate, and so on.

With none of the esters does the previous addition of hydrogen to the ester vapor appear to cause any change in the mechanism of the decomposition or in the nature of the products formed. That this is true is indicated by the fact that for each ester the ratio of the percentages of each product formed when hydrogen is initially absent to that formed when hydrogen is previously added is approximately a constant. This seems to be conclusive proof that the added hydrogen acts merely as a diluent.

A comparison of the data in the columns designated, (old), with similar data for the same temperature shows the effect of continued use of the catalyst on the decomposition products of the esters. This effect was investigated because it was observed early in the work that the proportions of the products obtained varied greatly with the age of the catalyst. The samples of the catalyst from which the recorded data were obtained had been previously used for about four hours at the given temperature. These samples were first washed with pure hydrogen for several hours at the same temperature. Finally, the ester vapor was again passed over the catalyst and the products were collected and analyzed as before. The percentages of carbon dioxide and methane in the gaseous mixture are less, while those of carbon monoxide and hydrogen are greater than in the mixtures obtained with a freshly prepared catalyst. The fact that these changes in the composition of the resulting products obtained from successive experiments with the same sample of catalyst are so marked is sufficient evidence of a rapid change in the nature and the activity of the nickel. This change in activity may be due in part to the well known poisoning effect of carbon monoxide. The change may also be

due to the deposition of other decomposition products on the surface of the nickel. That this may be true is evidenced by the fact that there is always deposited at the end of the tube a dark brown tarry film of unknown composition. Further, the nickel assumes a grayish color and dissolves in dilute hydrochloric acid much more slowly than does freshly prepared nickel.

At the lowest temperature indicated for each ester the percent of ester vapor decomposed is small, usually less than 10 percent of the ester used; the amount decomposed increased to 80 percent and above at the higher temperatures. The temperatures at which the various esters begin to decompose were found to be approximately as follows: methyl acetate, 310° ; ethyl acetate, 280° ; propyl acetate, 330° ; methyl propionate, 360° .

Summary

The products of the catalytic decomposition of methyl, ethyl and propyl acetates, and of methyl propionate by finely divided nickel have been studied at various temperatures between 300° and 725° .

The approximate temperatures at which the different esters begin to decompose have been determined.

For all the esters studied the proportions of carbon dioxide and methane in the decomposition products were found to increase with rise in temperature; those of hydrogen and carbon monoxide decrease under the same conditions. Only traces of hydrocarbons higher than ethane were ever found. No free acid or other liquid decomposition products appeared at any temperature.

The addition of hydrogen to the vapors before passing over the nickel produces no change in the nature of the decomposition products, indicating that the mechanism of the reaction is the same with or without added hydrogen. Hydrogen is formed in the decomposition.

The activity of the catalyst is altered by some of the products resulting from the decomposition of the ester.

A scheme representing the catalytic decomposition of esters by nickel has been suggested.

THE DECAY OF PHOSPHORESCENCE OF ZINC SULPHIDE

BY H. AUSTIN TAYLOR¹

The uncertainty attached to a study of phosphorescent phenomena, despite the large amount of work already accomplished is multiplied by the diversity of opinion on what would seem to be the very fundamentals. The question, for example, as to whether some exciting element present as impurity in the phosphorescent material is a necessity for phosphorescence does not seem, even at the present time, to have been satisfactorily settled. There is evidence on this point from both directions. Again, the question of the cause and rate of decay of phosphorescence has no thoroughly satisfactory answer and both theory and practice have supporters whose ideas are mutually contradictory and conflicting. The cause of such a situation would appear to lie in the fact that the experimental work so far performed has not in many cases been of the highest order and the results obtained generalised to too great an extent, thereby involving error.

The complexity of the problem of phosphorescence then, necessitates an attack on a small portion of the phenomena first, and it is proposed herein to study the effect of temperature on the rate of decay of phosphorescence using zinc sulphide as the phosphorescent material.

The similarity between this effect and that of red and infra-red radiation suggests at once that a similar explanation holds for both. Such a suggestion has already been made by Perrin² and experimental evidence quoted in its favor, the whole being taken as evidence in favor of the simple radiation theory of chemical reaction. The doubt recently cast on this theory from numerous points of view necessitates a critical examination of the evidence from phosphorescence.

According to Perrin, phosphorescence is due to the emission of radiation by the phosphorogen returning to the normal state from the modified or excited state into which it was thrown by absorption of the exciting radiation. That the frequency of the phosphorescent radiation is in general lower than that of the exciting light³ is explained by the assumption that the return from the excited to the normal state is a process occurring in numerous stages, each accompanied by its own emission and therefore of a lower order than the excitation which presumably occurs in one step. The cause of the return of the excited molecule to the normal state is to be found in the internal radiation present in the system in virtue of its temperature. If the temperature of the system is raised, the rate of return is increased, that is, the phosphorescence is increased. Alternatively if we increase the internal radiation

¹ Contribution from the Havemeyer Chemical Laboratory, New York University.

² *Trans. Faraday Soc.*, 17, 566 (1922).

³ Stokes' Law.

of the system photochemically, as opposed to thermally, we shall again increase the rate of return of the excited molecule to its normal state, again increasing the phosphorescence.

Qualitatively the explanation appears to agree with the observed facts. Perrin however proceeds to make the theory quantitative. The regeneration of the normal phosphorogen is considered as a unimolecular chemical reaction and its rate thus measurable at different temperatures. From the temperature coefficient of this rate of decay of phosphorescence the energy of excitation,—the critical increment,—may be calculated in the usual manner and hence the frequency of radiation which should cause the more rapid decay. Perrin writes: "I have done this recently in the case of phosphorescent zinc sulphide containing copper. Measuring the increase in the brightness produced by a known rise of temperature I have succeeded in calculating the wave length, approximately 1μ of the regenerating radiation. It remains to be seen whether this infra-red radiation really regenerates the phosphorogen. . . . The spot hit by these rays of wave length 0.7 to 1.5μ emits a bright phosphorescence and very soon afterwards that spot turns dark and is then easily distinguished again from the faintly luminous background." The evidence seems unequivocal.

When we analyse the data recorded before that of Perrin however, we are immediately struck by some apparent anomalies if the theory suggested is the correct one. The experiments of Becquerel more than fifty years ago showed definitely that the radiation causing the more rapid decay of phosphorescence was not confined to a single frequency nor even a narrow band of frequencies such as the radiation theory would demand, but was general throughout the red and infra-red regions of the spectrum. More quantitative experiments of Nichols and Merritt¹ on the decay of zinc sulphide phosphorescence at different temperatures showed that the effect of temperature over large ranges is a complex effect and not at all in agreement with the unimolecularity assumed by Perrin. It was found then, that the rate of decay—temperature curve showed various maxima, one at some temperature above 20°C , another, very pronounced, at -40°C and a third at -160°C . The existence of such maxima necessarily means that the temperature coefficient of decay is negative for certain ranges; a fact hardly capable of reconciliation with Perrin's view. That such behavior could be explained on the basis of complexity of phosphorescence bands does not seem possible in view of the work of Pierce² in the same year, wherein he finds no change in the phosphorescent band position, either with progressive decay, under the action of infra-red radiation, or with a temperature change, and it would not seem probable that the effect of either infra-red or temperature would be the same on each component of a complex band. Ives and Luckiesh³, too, have shown that the effect of infra-red is one of total emission and not of a separate band or part

¹ Phys. Rev., **32**, 38 (1911).

² Phys. Rev., **32**, 115 (1911).

³ Astrophys. J., **34**, 173 (1912); *ibid.*, **36**, 330 (1912).

of the radiation, although they point out that the intensity of the phosphorescence is directly proportional to that of the red or infra-red radiation causing the abnormal decay.

Here again the general evidence so far forthcoming is conflicting and at times contradictory. Lenard¹ and his co-workers have shown definitely that, in the phosphorescence, three different processes may be distinguished, one of very short duration, one of medium duration and one of very long duration. Such being the case it is not to be expected that the direct observations as made should bear of a very simple explanation.

It was proposed therefore to study again the effect of temperature, over a limited range, on the rate of decay of zinc sulphide phosphorescence and to compare this rigorously with the action of radiation as Perrin suggests.

Experimental and Results

The method adopted in obtaining the temperature coefficient of phosphorescent decay was to measure the time taken for a sample of zinc sulphide, saturated with the exciting radiation, at a known fixed temperature, to decay to a fixed photometric standard. The comparison between the intensity of the zinc sulphide screen and that of the standard was made possible by use of a photometer in which the screen was viewed directly through a circular glass plate which carried at its center a small right-angled prism, the latter reflecting the light of the photometric standard. The field of view thus obtained was a square of fixed color and intensity surrounded by the light from the phosphorescing screen. When the field presented an even appearance the intensity of the phosphorescence was identical with that of the standard. The arrival at this point was accurately observable by the disappearance of the line of demarcation between the two lights.

The arrangement of the apparatus was as follows: the zinc sulphide screen was enclosed in an oven, the temperature of which was automatically regulated to $\pm 0.1^{\circ}\text{C}$. The oven carried two windows, one of glass through which the phosphorescence was observed and one of quartz so that the exciting radiation when necessary could be in the ultra-violet region. A shutter was placed immediately in front of this latter window and served to cut off the exciting light as desired. Observation of the phosphorescence was made as stated, through the photometer using a solution of suitable color illuminated by a small electric light as standard for comparison.

The samples of phosphorescent zinc sulphide were five in number. Three, containing copper, exhibited a bluish green phosphorescence; the fourth was yellow, whilst the fifth had a distinctly red phosphorescence. The samples were obtained from various sources and their composition and method of preparation was not known.

As sources of exciting radiation the Kromayer quartz mercury lamp was used for ultra-violet alone, the visible being excluded by means of a nickel glass screen. For visible radiation as exciting source two tungsten filament

¹ Ann. Physik, 1904 et seq.

lamps (250 watts) were used, one with a plain glass bulb and the other with a blue glass bulb, the familiar day-light lamp, which transmitted therefore less red light than the former.

The experimental procedure consisted first in allowing the sulphide screen at a fixed temperature to become saturated with the exciting radiation, which was then cut off by means of the shutter, at the same instant a stop-watch being released. The moment that an even field was obtained in the photometer, was registered on the watch and the interval for the decay of phosphorescence noted. This measurement was then repeated from ten to twenty times and the average value at that temperature taken. The temperature of the oven was then raised a known amount and the process repeated using the same intensities of radiation for both the exciting source and photometric standard as at the lower temperature. In this manner the times of decay were obtained at a series of temperatures from room temperature to 110°C . The same process was then repeated using the other sources of excitation and the temperature coefficients found under the different conditions. Other samples of zinc sulphide were then substituted and similar measurements made.

Table I gives the times of decay to standard intensity for the various samples at the temperatures indicated. The graph accompanying these, Fig. 1, is typical of the others.

TABLE I
Times of Decay in Seconds
Zinc Sulphides

Temp. $^{\circ}\text{C}$	Green A Kromayer Lamp	Green A Tungsten Lamp	Green A Daylight Lamp	Green B Tungsten Lamp	Green C Tungsten Lamp	Yellow Tungsten Lamp	Red Tungsten Lamp
25		19.00	10.60	24.00	23.00	11.80	8.40
30	7.40						
35		16.60	9.00	20.00	20.40	10.60	7.40

90	2.55						
95		4.90	2.30	6.20	9.20	5.60	3.40
100	2.00						
105		3.40	1.60	4.60	7.80	5.20	3.00
110	1.60						

The average temperature coefficients corresponding to these times of decay and calculated directly from them are given in the following table.

TABLE II

Sample and Exciting Source	Mean Temp. Coef.
Green A. Kromayer Lamp.	1.20
Green A. Tungsten Lamp.	1.24
Green A. Daylight Lamp.	1.25
Green B. Tungsten Lamp.	1.25
Green C. Tungsten Lamp.	1.15
Yellow. Tungsten Lamp.	1.12
Red. Tungsten Lamp.	1.14

The reliability of these mean values may be seen from the detailed calculations shown in Table III which gives the temperature coefficients per 10°C throughout the range of temperatures studied.

FIG. 1

TABLE III

ZnS. Green A. Kromayer Lamp as Excitor

Temp. Range in $^{\circ}\text{C}$	Temp. Coef.	Temp. Range in $^{\circ}\text{C}$	Temp. Coef.
30-40	1.17	70-80	1.23
40-50	1.17	80-90	1.21
50-60	1.19	90-100	1.28
60-70	1.20	100-110	1.25

Mean 1.20

The variation of these values from the mean may be either real or apparent, that is to say, there may actually be a variation in the temperature coefficient, or, the error involved in the measurement of the times of decay at the higher temperatures, which is of the order of two seconds, may account for it. That the former is more probably the case is suggested first by the results themselves, in the general rising trend of the temperature coefficients with a rise in temperature, shown not only in the instance quoted but in every case studied. Secondly, the work of Lenard already mentioned, having shown the complexity of the total phosphorescent process, would suggest a change in the temperature coefficient with a change in temperature since in all probability the long and short phosphorescences will not have the same temperature coefficient and one or other would predominate at the higher temperatures.

As regards the actual measurement of the time of decay even at the higher temperatures where the times are short, the general smoothness of the curves obtained may be taken as qualitative evidence of their reliability. Actually however the degree of precision for the average of the twenty readings taken at one temperature is ± 5 percent at the higher temperatures and may fall to as low as ± 1 percent at room temperatures where the times are much longer.

The similarity then, between the temperature coefficients of decay in the first three instances in Table II where the same sample of zinc sulphide was used and the same photometric standard used for comparison indicates that a change in the source of exciting radiation is without any appreciable effect on the phosphorescent process.

That the phosphorescence itself is complex may be indicated by a study of the same sample using a different standard for comparison. The following table gives the times of decay for the sample Green A using a more feeble intensity in the photometer for comparison. The times it will be noted are therefore much longer.

TABLE IV
ZnS. Green A. Tungsten Lamp as Excitor

Temp. °C	Time of decay. Seconds	Temp. °C	Time of decay. Seconds
25	10.80	75	5.35
35	9.50	85	4.50
45	8.35	95	3.70
55	7.30	105	3.00
65	6.30		

The mean temperature coefficient calculated from these values is 1.18 as compared with the value 1.20 obtained from a study over a shorter period of the phosphorescence. The same effect namely a slightly lower temperature coefficient was observed in two other cases studied when a more feeble standard was used for comparison, which would point to the fact that the phosphorescent process of long duration had a lower temperature coefficient than the process of shorter duration. This in turn is in line with the increase in temperature coefficient with an increase in temperature since it is the phosphorescence of shorter duration which is more affected by an increase in temperature.

The temperature coefficients for the different samples as shown in Table II would suggest that there exists some relation between the color of the phosphorescence and the temperature coefficient. The results 1.12 for the sample phosphorescing yellow and 1.14 for the red, are both lower than the green samples. Remembering that the temperature coefficient is lowered in general by an increase in the period of decay studied there would appear to be a progressive fall in the temperature coefficient as the phosphorescence passes from green to red. It is hoped at a later date to study this problem further.

The feature of prime importance however, which these results have brought out is the order of magnitude of the temperature coefficient of decay. If we take the value 1.20 as a mean value of all the samples, the smallness of

this as a temperature coefficient is remarkable. Such a value is at once suggestive of a photochemical process rather than of a thermal process, and is much lower than the figure quoted by Perrin. Using the simple radiation theory in the manner previously suggested we find that the temperature coefficient of 1.20 corresponds to 4300 calories in the mean temperature range 65-75°C, or to a wave length 6.65μ in the short infra-red. The difference between this value 6.65μ and that which Perrin gives, namely 1μ , calls immediately for explanation.

Perrin tells us that on exposing an illuminated zinc sulphide screen to a spectrum of radiation the spot hit by the rays of wave lengths 0.7 to 1.5μ phosphoresces more brilliantly than the rest and eventually becomes dark. The uncertainty of definitely identifying the wave length of a band in such a crude experiment suggests at once that the region was probably much larger and that even though a very narrow band was responsible for the darkening, the overlapping of spectra would cause an apparent broadening. It seemed advisable therefore to try the effects of practically monochromatic radiation at various points in the spectrum and thereby to isolate the effective wave length, if such exists.

The first wave length tested was that calculated from the temperature coefficient namely, 6.65μ . This was obtained by means of a Hilger Infra-red Spectrometer using a carbon arc as source of illumination and rock salt prism as dispersing agent. The intensity of the practically monochromatic radiation at 6.65μ although feeble was still sufficient to cause a more rapid decay of the phosphorescence of the zinc sulphide screen, as shown by a black line—the image of the spectrometer slit—on the faintly phosphorescing background. The result appears then, to be in agreement with the radiation theory. On turning the prism, however, almost indiscriminately, it was found that the same result was obtainable at any wave length in the short infra-red. Apparently a single frequency of radiation is not alone active, and it was decided to try the effects of various screens.

The first screen was the biotite mica screen used previously¹ which transmitted radiation from about 2μ up to 8μ only. The zinc sulphide screen was illuminated over its whole surface, half of it was then covered and the remaining half exposed to the infra-red radiation for a few seconds. It was found that the half which had been exposed was much darker than the unexposed portion.

In order to pass further into the infra-red it was necessary to find a screen which absorbed in the near infra-red but which became transparent again in the further region. It seems remarkable that sphalerite itself is such a substance. Coblenz² states that a crystal 1.5 mms. thick is transparent from 5μ to 12μ and is entirely opaque at 15μ . A thin plate of sphalerite was obtained and used as a filter in a manner similar to the biotite. The result was again the same, showing that apparently any wave length in the short infra-red is capable of causing a more rapid decay of the phosphorescence.

¹ J. Am. Chem. Soc., **48**, 577 (1926):

² Carnegie Inst. Pub., No 65 (1906).

Using a ruby glass filter the result was likewise the same, that is there was a more rapid decay of the phosphorescence and the part exposed to the red light was darker than the unexposed portion. A yellow filter obtained by interposing a solution of picric acid in water between the light source and the phosphorescing screen also caused a darkening more rapidly than with the normal rate of decay.

In all these cases the sample of zinc sulphide used had been the sample A which phosphoresced green. A green filter was therefore used to see what the effect would be. The filter was identical with the one which had been used as the comparison standard in the photometer in the previous experiments and was a solution of nickel and copper nitrates in water. It was found that when the light filter was sufficiently concentrated to give a color on the non-phosphorescing zinc sulphide, of the same intensity as the normal phosphorescence without the filter, then practically no phosphorescence of the screen was caused and no increased darkening was observed with the phosphorescing screen. If this filter is diluted with water, some phosphorescence is caused, presumably owing to the shorter wave lengths which are transmitted by the more dilute filter. If however, the filter is made more concentrated, an increased darkening action can be observed with a zinc sulphide screen which is already phosphorescing.

From these experiments it is apparent, first, that Stokes' Law is being obeyed, and second, that any radiation of wave length shorter than the mean phosphorescent wave length is capable of causing a more rapid decay of the phosphorescence.

This is further confirmed by experiments with the other samples of zinc sulphide which phosphorescence at different regions. Taking (1) the green sample A, (2) the yellow and (3) the red phosphorescent zinc sulphides and constructing light filters of (1) nickel and copper nitrates (2) picric acid and (3) potassium dichromate solutions respectively, such that the light transmitted by these was of approximately the same intensity as the normal phosphorescence of each of the three samples, it was found that the green filter (1) though without action on the green sample was capable of causing phosphorescence of both the yellow and red samples of zinc sulphide. Filter (2) of picric acid would cause the red zinc sulphide alone to phosphoresce, but also caused a darkening of the phosphorescing green sample more rapidly than normal. Filter (3) of potassium dichromate whilst inactive towards the zinc sulphide which phosphoresced in the red was capable of causing a more rapid decay of the phosphorescence of both the green and yellow samples.

It is obvious then that the line of demarcation between ability to cause phosphorescence and ability to cause the decay of phosphorescence is quite sharp. Wave lengths shorter than this line will all cause phosphorescence whilst all wave lengths longer than this line will cause a more rapid decay. The requirements of the simple radiation theory are not at all satisfied.

What the true explanation of these results is, it is hoped to make the subject of a subsequent paper. The fact that the magnitude of the temperature coefficient would seem to point to a photochemical rather than a thermal

reaction suggests that a physical explanation is probable, and that purely chemical effects only enter in cases of extreme illumination such as the blackening of zinc sulphide by intense ultra-violet light, as studied in detail by Lenard¹. There, the bond between the atoms in the molecule is completely severed and free zinc remains. That such a profound change is required for phosphorescence does not seem likely, rather would an electron shift within the zinc sulphide molecule account for the results.

Summary

1. The contradictory nature of the data on the effect of temperature on the rate of decay of zinc sulphide phosphorescence is pointed out.
2. The temperature coefficient of the rate of decay of phosphorescence has been measured for five different samples of zinc sulphide under varying conditions.
3. Analysis of the data shows the temperature coefficient to be 1.20 per 10°C in the neighborhood of 70°C corresponding to a wave length of 6.65 μ on the basis of the radiation theory. The difference between this and Perrin's figure of 1 μ has been noted.
4. It has been shown that the abnormal decaying effect of radiation on zinc sulphide phosphorescence is not confined to a particular frequency, nor to a particular region of the spectrum, but that all frequencies incapable of causing phosphorescence will cause its more rapid decay. Further work is in progress.

THE METHANE EQUILIBRIUM. II

BY R. C. CANTELO

It is quite conceivable that when ethylene is subjected to thermal decomposition, we might have any or all of the reactions indicated below, proceeding either simultaneously or successively. For convenience, the equations have been written in such a way that the left-hand side is a single hydrocarbon.

Now it is quite possible to apply the Phase Rule to such a series of equilibria. At a sufficiently high temperature, the maximum number of phases is two, the gas and the solid, the variants are fixed as temperature and pressure; and the number of components is evidently two. Hence the equation $N - R + 2 = V$ is satisfied. (N =no. of components, R =no. of phases, and V =the variants.) The conclusion is reached therefore, that whether the initial system be methane, ethylene, or ethane, the final system must be one in equilibrium. This system may consist of any or all of the substances indicated, but each of these compounds must be present in such a proportion as to present a "symphony of equilibria" amongst them all.

The question now arises whether it is possible to predict the quantitative composition of the equilibrium system for a definite temperature and pressure. To answer this question it is necessary to turn to Thermodynamics for criteria of equilibrium and the simplest is evidently the free energy function. Gibbs¹ states that for any isothermal and isobaric process

$$(\delta\xi)_{T,P} \geq 0$$

i. e., the free energy is continually tending towards a minimum; and finally for a system in neutral equilibrium, the free energy change is zero.²

Now if it were possible to calculate the free energy decrease attending the synthesis of each of the hydrocarbons considered above, it could be said that where the decrease is positive, the final system is the stable one; and where, on the other hand, the free energy had increased, it would be necessary to state

¹ "Thermodynamics," 91 (1906).

² This is really Gibbs' Thermodynamic Potential.

that the final system was an unstable one. For example, Lewis and Randall¹ have calculated the free energy decrease ($-\Delta F$) attending the synthesis of methane from graphitic carbon and hydrogen, and find it to be +12,800 calories. This means simply that methane is a stable compound, a fact borne out by numerous experimental investigations. No such data exist for the other compounds considered above.

But it is not necessary to stop at this point. The free energy of such a reaction as

is given by the expression

$$-\Delta F = RT \left\{ \ln K_p - \ln \frac{p'_e \cdot p'_f}{p'_a \cdot p'_b} \right\}$$

which, as shown, involves the equilibrium constant. If now, the pressure quantities in the second term within the bracket be made each arbitrarily equal to 1 atmosphere, the expression simplifies to

$$-\Delta F = RT \ln K$$

So that we have in the equilibrium constant, a criterion for the stability of each of the various systems under consideration.

Again the van't Hoff equation

$$d \ln K_p = \frac{\Delta H}{RT^2} \cdot dT$$

should enable K_p for a given reaction to be calculated when ΔH , the increase in heat content attending the reaction, is known. But the above relation is really a differential equation and its integration will involve some unknown constant of integration. The simplest solution lies in the use of approximate expressions, of which the Nernst Approximation² has been most successful.

$$\log K = \frac{-\Delta H}{4.571 T} + \Sigma v \cdot 1.75 \log T + \Sigma v C$$

ΔH = increase in heat content of the system as written in the thermochemical equation.

Σv = change in the number of molecules formed by the reaction.

$\Sigma v C$ = the summation of the "chemical constants of the reacting substances existing only in the gaseous state."

Table I gives the values for K_p at different temperatures for each of the equilibria considered above. The values for ΔH were calculated from the heat contents of the various compounds involved.

¹ "Thermodynamics," 607 (1923).

² "Experimentelle und theoretische Grundlagen des neuen Wärmesatzes," (1918).

TABLE I

Reaction	ΔH	K_{200}	Approximate K_{400}	K_{600}	K_{800}
(1) $C_2H_4 \rightleftharpoons 2C + 2H_2$	-14,600	6.9×10^{11}	1.2×10^{10}	1.2×10^9	4.8×10^8

(5) $C_2H_4 \rightleftharpoons C_2H_4 + H_2$	37,900	8.7×10^{-12}	2.8×10^{-6}	2.1×10^{-3}	1.9×10^{-2}
(6) $C_2H_6 \rightleftharpoons C_2H_2 + 2H_2$	81,400	3×10^{-25}	1.7×10^{-13}	6.6×10^{-7}	7×10^{-3}
(7) $3C_2H_2 \rightleftharpoons C_6H_6$	-163,000	2.6×10^{59}	3.1×10^{86}	7.6×10^{83}	10^{22}
(8) $CH_4 \rightleftharpoons C + 2H_2$	18,900	6.4×10^{-4}	3.2×10^{-1}	13	142
(9) $2CH_4 \rightleftharpoons C_2H_4 + 2H_2$	52,400	3.1×10^{-19}	8.9×10^{-12}	1.2×10^{-7}	2.4×10^{-4}
(10) $2CH_4 \rightleftharpoons C_2H_2 + 3H_2$	95,900	1.6×10^{-32}	6.4×10^{-19}	2×10^{-11}	1.2×10^{-6}

It must be emphasized that no single reaction may be considered exclusively by itself. All the above reactions must be considered as vitally interrelated, and the calculated values of K_p must be reviewed with respect to all possible systems.

A consideration of reactions (1), (2), (3), (5), (9) shows that the initial system ethylene tends to pass to an equilibrium system involving carbon, hydrogen, ethane, benzene, and methane.

Reactions (4), (5), (6), (8) show that the initial system ethane tends to pass to an equilibrium system, carbon, hydrogen, and methane; but ethane is fairly stable up to 400°C.

Reactions (8), (9), (10) show that the sole tendency in the temperature interval 200-800°C. is for the initial system methane to pass to the final system (in equilibrium) methane, carbon, and hydrogen.

There is little tendency in these three systems to give acetylene (at equilibrium) so that equation (10) need not be considered.

The question now arises whether benzene will be stable over this temperature interval.

These values indicate that benzene should not exist over this temperature interval. In this connection it is interesting to note that Sabatier¹ states with respect to the direct hydrogenation of benzene in the presence of metallic nickel that above 200° and especially "au delà de 300°, une partie du benzène est hydrogénée en méthane, et il y a dépôt d'un peu de charbon sur le nickel."

It must be emphasized again that the above deductions are based upon the assumption that sufficient time elapses to give an equilibrium state. This may be one second or a million years!

The final conclusion from the above consideration of equilibrium constants is that whether the initial system be methane, ethylene, or ethane, the final equilibrium system will be methane, carbon, and hydrogen in the proportions required to satisfy this equilibrium. But "man kann nicht mathematisch beweisen dass die Natur so sein müsse, wie sie ist." Can the above be shown experimentally?

The next paper of this series will discuss experiments performed with a view to obtaining the methane equilibrium with ethylene as the initial system.

For the present it is interesting to review briefly the more modern work upon the thermal decomposition of ethylene. Bone and Coward² carried out what was probably the most valuable investigation on thermal reactions of ethylene. They circulated ethylene for a period of 2½ hours through a tube heated to 570°-580°C. Acetylene, ethane, methane, and hydrogen were produced but the quantity of carbon separated was negligible. Methane ac-

¹ "La Catalyse en Chimie organique," 171 (1920).

² J. Chem. Soc., 93, 1197 (1908).

cumulated during the first 60 minutes and then decreased slightly; acetylene varied irregularly from 12% of the gases after two minutes heating to 6% of the gases at the end of the experiment.

The importance of the time factor is shown especially well in Table II taken from their work on the decomposition of ethylene at 800°C.

TABLE II

Time in minutes	1	5	15	60
% C_2H_2	3.00	23.9	3.85	nil
% C_2H_4	57.25	1.4	9.65	0.9
% C_2H_6	3.25	5.0	1.3	nil
% CH_4	29.4	53.4	64.45	67.7
% H_2	7.1	17.0	20.75	31.4

It is evident that this table adds confirmation to the theoretical conclusions of the writer.

When ethylene was heated to 950°C., 90% decomposed within one minute, and all was decomposed after 15 minutes. Small amounts of aromatic hydrocarbons were produced, but large quantities of carbon separated. The gases were methane and hydrogen. At 1100°C., ethylene was rapidly and completely decomposed into carbon, methane, and hydrogen.

Sabatier and Senderens¹ have studied the thermal decomposition of ethylene in the presence of catalysts.

When ethylene was passed with moderate rapidity, over nickel obtained from its oxide by hydrogen, and heated to a temperature not exceeding 325°C., the issuing gas was a mixture of 10 volumes of hydrogen with about 60 volumes of ethane and 30 volumes of methane. At higher temperatures the proportion of ethane diminished and only traces remained when the temperature was that of red heat. It appeared that the first change in the decomposition was the formation of carbon and ethane, the latter at higher temperature decomposing into carbon and hydrogen. Direct experiments showed that ethane was partially decomposed by nickel at 325° and that methane was decomposed especially above 390°C.

Sabatier also makes the statement:—"Avec une colonne assez longue de nickel réduit, ou un courant suffisamment lent d'éthylène, on peut arriver dès 325° à une transformation à peu près complète en formène, mêlé d'un peu d'hydrogène. Il serait beaucoup moins aisé d'attendre la décarburation totale du formène, celle-ci n'étant pas encore très rapide au rouge sombre." The following statement should also be quoted as it has a confirmatory bearing upon the theoretical conclusions:

"Les gas recueillis ne contiennent pas en proportion appreciable de gas absorbable par le brome, et ne donnent pas de réaction avec la solution ammoniacale de chlorure cuivreux: ils ne renferment donc aucunes doses mesurables

¹ Compt. rend., 124, 616, 1358 (1897); 131, 267 (1900).

de carbures éthyléniques ou acétyléniques. Ils sont constitués par un mélange d'hydrogène et de carbures forméniques." Again "dans aucun cas . . . nous n'avons pu condenser dose perceptible de produit liquide."

Finely divided platinum and copper have no action on ethylene below 400°C., but cobalt above 300° partially decomposes it into ethane, methane, and hydrogen together with carbon, but without any acetylene. Iron above 350°C. has less action but decomposes a part of the gas into ethane, hydrogen, and carbon.

When a mixture of hydrogen with an excess of ethylene is passed over reduced nickel heated to a temperature not exceeding 150°C, ethane is the sole product of the reaction. This reduction of ethylene to ethane at 150°C., furnishes an interesting example of the utility of the calculated equilibrium constants in prophesying the course of a reaction.

$$K_{150} = \frac{P_{\text{C}_2\text{H}_4} \cdot P_{\text{H}_2}}{P_{\text{C}_2\text{H}_6}} = 6 \times 10^{-14}$$

That is, the numerator is exceedingly small, indicating complete transformation to ethane.

On account of the fact that ethane is usually formed by the thermal decomposition of ethylene, the work of Bone and Coward⁴ on the thermal decomposition of ethane should be mentioned at this point.

In one experiment ethane was circulated through a tube heated to 675°C. The results of this experiment are given in Table III.

TABLE III

Times in hours	C_2H_2	C_2H_4	C_2H_6	CH_4	H_2
0.5	4.1	24.7	34.7	8.4	28.1
1.5	5.1	24.1	9.8	19.9	41.1
3.0	2.8	16.4	7.3	32.9	40.6
6.0	1.9	0.7	2.0	54.5	40.9

At 800°C., ethane decomposes rapidly. In one minute's heating, the gas had the composition acetylene, 1.9%; ethylene, 11.2%; ethane, 17.9%; methane 31.3%; and hydrogen, 37.7%. After one hour's heating, only methane and hydrogen remained. Similar results were obtained at the higher temperatures.

A perusal of the above brief review of the work upon ethylene and ethane shows that the conclusions drawn by the writer from the calculated equilibrium constants, are supported by experimental investigations. As Bone has pointed out, in the majority of investigations, the time factor has been neglected. His own work, however, shows that with increasing time, the initial system approaches nearer and nearer to neutral equilibrium.

Summary

Calculations of equilibrium constants for the possible reactions involved in the decomposition of methane, ethylene, and ethane indicated that above 400° , the final system should be one of methane, carbon, and hydrogen, irrespective of which hydrocarbon was used as the initial system.

A review of the literature on the decomposition of ethylene and ethane, both by heat alone and in the presence of catalysts, showed that the experimental results of previous investigators were in harmony with the conclusions drawn from the calculated equilibrium constants.

THE HYDROGEN ELECTRODE IN THE STUDY OF THE RATE OF SAPONIFICATION OF OILS AND FATS BY AQUEOUS ALKALI

BY J. W. MCBAIN, H. S. HOWES AND MURIEL THORBURN

The only available measurements of the rate of saponification of triglycerides or commercial oils and fats by aqueous alkali are those of Norris and McBain¹ and of H. Langton.² Measurements of this type are, however, all open to the serious criticism that when the reaction is allowed to proceed from beginning to end, numerous changes of state occur. Thus, inspection of the diagrams of phase rule equilibria of soaps now available shows that six different sets of phases may be present at different stages of the reaction. Not only so but the concentrations of all the substances are continually changing including any emulsifiers as well. Hence, there are insufficient data available upon which to judge whether it might be industrially preferable to carry out saponification in "crutchers" with concentrated alkali before putting the resulting soap into the soap pan.

Previous work showed that the rate of reaction is almost entirely dependent on the rate of movement of alkali to and of the products of reaction from the surface of the droplets of oil, and it indicated the factors which are involved and even some of their effects. However for any real advance it was necessary to devise a new method such as is described in the present investigation.

It has been found possible to vary one factor at a time keeping all the others constant³ and thus to isolate and determine the effect of each factor. Each of the reagents except the hydroxide is kept in sufficiently large excess to be appreciably constant throughout any one experiment thus keeping all the physical, as well as chemical factors, constant.

It is found that the hydrogen electrode is actually able to follow the rate of disappearance of the dilute hydroxide. This obeys a monomolecular law in so far as hydroxyl ion is concerned and the results are surprisingly reproducible. We have thus a rapid and quantitative method for measuring the rate of saponification under all conditions. The quantitative information here obtained substantiates the conclusions indicated in the previous communication. It is now a simple task to extend these results so as to obtain representative data for a large number of pure triglycerides as well as commercial materials. The results here recorded refer chiefly to coconut oil together with a few data for trilaurin and tripalmitin.

¹ J. Chem. Soc., **121**, 1362 (1922). Treub has called our attention to papers by himself (J. Chim. phys., **16**, 107 (1918), Rec. Trav. chim., **42**, 556 (1923). However, they do not contain any actual measurement of rate, but only surmise and mathematical formulations which in part do not find confirmation in our experiments.

Experimental

Chemicals used.

Standard solutions of sodium hydroxide were made by dissolving sodium drippings, free from carbon dioxide, in boiled out distilled water. The solutions were standardised by titration against standard hydrochloric acid (made by the method of Hulett and Bonner¹) and kept in flasks fitted with vaselined stoppers.

The oils used were of two kinds—pure and commercial. The pure triglycerides, trilaurin and tripalmitin, were supplied by Kahlbaum. The commercial coconut oil used was obtained through the kindness of Chris. Thomas and Bros. Ltd, and had been carefully neutralised by them. On keeping for many months however, it tended to become very slightly rancid and was therefore again neutralised before use by heating with aqueous sodium hydroxide, and was subsequently washed free from alkali with boiling distilled water.

Sodium laurate and sodium palmitate were obtained from Kahlbaum. Coconut oil was saponified with alcoholic sodium hydroxide, and soap formed was decomposed with sulphuric acid and the fatty acids thoroughly washed with boiling water and dried at 100°. From them coconut oil soap was prepared by the method of Bunbury and Martin.²

Method of measurement of rate of reaction.

The hydrogen electrode was coupled with a decinormal calomel electrode as follows:—

Pt H ₂	Sapon ^a . mixture	$\frac{1}{2}$ satd. KCl	$\frac{1}{2}$ satd. KCl	0.1N _v KCl satd. with Hg ₂ Cl ₂	Hg ₂ Cl ₂ (solid)	Hg
90°	90°	90°	room temp.	room temp.	room temp.	room temp.

As the potential of the calomel electrode remains constant throughout, the rate of change of E. M. F. of this cell is nearly proportional to the rate of saponification as is shown below, under the heading "Calculation of Results."

Apparatus employed.

Saponification was carried out in a Pyrex, three-necked, round-bottomed flask of 500 cc. capacity (see Fig. 1). A stirrer passed through the middle neck. It consisted of a small silver propeller (made from a silver disc) bound on the end of a glass rod with silver wire, and was driven at a constant speed of 2400 r. p. m. by a small A. C. induction motor. The speed was frequently checked by a tachometer. The other two necks were utilised for the hydrogen electrode and the connection to the calomel electrode respectively. The reaction flask was about three-quarters immersed in a thermostat at 91° (± 0.10) the surface of which was covered with melted paraffin to prevent evaporation.

The hydrogen electrode was a slightly modified form of the Hildebrand type (see Fig. 1a). It was made by welding platinum wire to a piece of plat-

¹ J. Am. Chem. Soc., **31**, 390 (1909).

² J. Chem. Soc., **105**, 417 (1914).

inum foil about 1 cm. square and sealing the wire into a narrow-bore glass tube. This tube was two-thirds filled with mercury and connection made by an amalgamated copper wire dipping into the mercury. The outer glass tube was made of glass tubing of about $\frac{1}{2}$ " bore. It was closed at the top by a rubber stopper through which passed the inside tube. A small side-tube, sealed at right angles to the large outer tube just below the rubber stopper admitted hydrogen. Three circular holes about 1 cm. in diameter at the bottom of the large outer tube provided the hydrogen exit and enabled the reaction mixture

FIG. 1
Diagram of apparatus used.

to have free access to the platinum foil (see Fig. 1a). The electrode was cleaned by electrolysis it as anode in 3N hydrochloric acid solution, and then platinised by making it alternately anode and cathode with another platinum electrode in a solution of platinum chloride. An E. M. F. of four volts was used and the deposit of platinum black obtained was very fine and thin. Occluded chlorine was then removed by immersing the electrode in a solution of acidified ferrous sulphate and it was finally well washed with d'stilled water. The electrode did not require replating; it was cleaned in hot acid dichromate solution after each experiment and when not in use was kept in distilled water.

FIG. 1a
Section of hydrogen electrode.

The hydrogen supply was kept constant by means of a screw clip on a rubber tube which connected with a screwvalve of a cylinder of hydrogen. The hydrogen was allowed to pass through a safety flask and a flow indicator, and was saturated with water vapour by passing through a tube containing 0.1N_w sodium hydroxide at 90° (i. e. a solution of the same concentration as the alkali initially present in the reaction flask) from which it passed through a spray trap to the hydrogen electrode and thence bubbled through the reaction mixture. A small tube for the outlet of hydrogen passed through the cork of the second side neck of the reaction flask, which also carried the capillary siphon filled with half-saturated potassium chloride that formed the connection between the reaction mixture and an ordinary calomel electrode. The end of the capillary that dipped into the flask was drawn out to a fine

upturned point in order to avoid undue mixing of the potassium chloride with the reaction mixture. To lessen vibration of the capillary, an extension consisting of an ordinary piece of glass tubing was fitted to the neck carrying the capillary siphon (see Fig. 1).

A pycnometer calibrated to contain the required weight of $0.3N_w$ sodium hydroxide saturated with hydrogen at room temperature was used for measurement of the sodium hydroxide added to the reaction mixture.

For measurement of E. M. F. the ordinary compensation method of Poggendorf was used except that it was found more convenient to use a voltmeter instead of the usual standard cell. This was a Weston D. C. model and read to 0.001 volt. A capillary electrometer of the Lippmann type was used in obtaining the balance (see Fig. 1b).

Experimental procedure.

In each experiment in this investigation the effect of the concentration of oil and of soap was kept constant by initially adding both these constituents in large excess of the concentration of alkali. The rate during any given experiment was then proportional to the concentration of one reactant only (the alkali); it was then found to be a monomolecular reaction. Each experiment was carried out on a basis of 50 grams of water. Two thirds of the water was added with the soap and one third with the sodium hydroxide. All concentrations are expressed in weight normalities (the number of gram mols associated with 1000 grams of water).

Before every experiment the hydrogen electrode was tested in $0.1N_w$ sodium hydroxide at room temperature as follows:—

All at room temperature

If, after bubbling hydrogen through for about ten minutes an E. M. F. of about 1.083 volts (theory 1.089) was obtained the electrode was considered to be in order.

The requisite amounts of soap and oil were then weighed into the reaction flask and stirred at 90° for half an hour, hydrogen being bubbled through the whole time to ensure saturation. Meanwhile the hydrogen electrode was allowed to attain equilibrium in a $0.1N_w$ solution of sodium hydroxide at 90° . The potassium chloride siphon was then inserted and the required weight of saturated standard sodium hydroxide heated by placing the pycnometer containing it in the thermostat for about five minutes. It was then poured into the hot mixture of soap and oil, the hydrogen electrode inserted and E. M. F. readings taken every one or two minutes according to the speed of the reaction.

Calculation of results.

Since the progress of the reaction was followed by means of a hydrogen electrode, its E. M. F. is directly proportional to the logarithm of the concentration of hydroxyl ions or inversely proportional to the logarithm of hydrogen

ions, the two being connected through the constant ionic product at the constant temperature. Now for a simple monomolecular reaction the rate constant k should be equal to $1/t$ times the logarithm of the ratio of the initial concentration of the hydroxyl ions to that at time t . Hence, since the logarithm of the concentration of hydroxyl ion occurs both in the expression for rate and in the value of the E. M. F., the rate constant is proportional to $1/t$ times the change in E. M. F. up to time t . Therefore if the E. M. F. is plotted against time a straight line should result for a simple monomolecular reaction governed solely by the concentration of the hydroxyl ion. Actually however, although the rate is monomolecular the reaction is incomplete and reversible owing to equilibrium being obtained when the hydrolysis-alkalinity is of the order of $1/1000$. Therefore, although the change in E. M. F. is at first proportional to the time, the E. M. F. must ultimately tend to a constant value independent of time corresponding to the hydrolysis-alkalinity. This is illustrated by a typical graph in Figure 2 and we will now proceed to describe a very simple device by which all our results can be integrated without calculation, merely by correcting each point on the curve by amounts shown in Table I below. If the rate is really proportional to the concentration of hydroxyl ion this must result in a straight line as is shown in Fig. 2 and the slope of this straight line is the rate constant.

FIG. 1b

Potentiometer circuit.

AB = meter bridge wire.

C = sliding contact.

D = 2-volt accumulator.

E = capillary electrometer.

Let ξ be the equilibrium concentration of OH ions.

" a " " initial " " " " "

" x " " amount of OH ions reacting in a time t .

k_1 is the velocity constant of the forward reaction.

k_2 " " " " " back "

The rate observed is $dx/dt = k_1(a - x) - k_2x$

Then

$$\frac{1}{t} \ln \frac{a - \xi}{a - \xi - x} = k_1 + k_2$$

Putting the constant $(a - \xi) = n$ and $(a - x) = (\text{OH}')_t$

$$\ln ((\text{OH}')_t - \xi) = \ln n - (k_1 + k_2)t$$

as k_2 is small compared with k_1

$$k_1 + k_2 = k_1 \text{ (approx.)}$$

$$\text{i.e. } \ln ((\text{OH}')_t - \xi) = \ln n - k_1 t = \text{const.} - k_1 t$$

Therefore $\ln ((\text{OH}')_t - \xi)$ plotted against time should give a straight line to infinity if the reaction behaves as an incomplete or reversible monomolecular one.

$\ln ((OH')_t - \xi)$ expanded

$$= \ln (OH')_t - \frac{\xi}{(OH')_t} - \frac{\xi^2}{2(OH')_t^2} - \frac{\xi^3}{3(OH')_t^3}$$

$$\begin{aligned} \text{Now if } (OH')_t = 10, \ln ((OH')_t - \xi) &= \ln(OH')_t - \frac{1}{10} - \frac{1}{200} \\ &= \ln(OH')_t - 0.1053 \\ &= \log_{10}(OH')_t - 0.24255 \end{aligned}$$

0.24255 is thus the vertical error on a $\log (OH') : t$ graph where $\frac{(OH')_t}{\xi} = 10$

FIG. 2

Typical time/E. M. F. graph with 2 N_w coconut oil soap, 1 N_w coconut oil and 0.1 N_w NaOH at 90° showing correction for hydrolysis.

It is now necessary to express this vertical error in terms of E. M. F.

$$E_{(\text{corr.})} = E_{(\text{obs.})} + (\text{barometric correction} - (\text{correction to normal H}_2 \text{ electrode from calomel electrode}))$$

$$\begin{aligned} E_{(\text{corr.})} &= 0.0001985 T \log 1/(H') \\ &= 0.0001985 \cdot 363 \cdot \log 1/(H') \\ &= 0.07206 \log 1/(H') \end{aligned}$$

$$\text{But } (H') \text{ times } (OH') = K_w$$

$$\begin{aligned} \text{Therefore } E_{(\text{corr.})} &= 0.07206 \log (OH')/K_w \\ &= 0.07206 (\log(OH') - \log K_w) \end{aligned}$$

Let E_ξ be the hydrolysis E. M. F.

$$\text{Then } E_\xi = 0.07206 \log \xi - 0.07206 \log K_w$$

$$\text{and } E_{(\text{obs.})} = 0.07206 (\log(OH')_t - \log K_w)$$

$$\text{therefore } E_{(\text{obs.})} - E_\xi = 0.07206 (\log(OH')_t - \log \xi)$$

$$\text{or } \log \frac{(OH')_t}{\xi} = \frac{E_{(\text{obs.})} - E_\xi}{0.07206}$$

Correction to $E_{(obs.)}$ is therefore 72.06 times correction to $\log(OH')_t$ where $E_{(obs.)}$ is in millivolts.

The following table was drawn up for different values of $(OH')_t/\xi$.

TABLE I

$(OH')_t$	$E_{(obs.)} - E_{\xi}$ (millivolts)	Correction to $\log(OH')_t$	Vertical correction (millivolts)
20	93.75	0.052	3.747
10	72.06	0.24255	17.48
8	65.07	0.307	22.12
5	50.35	0.514	37.04
3	34.38	0.993	71.55

FIG. 3

Dependence of the rate constant (k) upon the concentrations of oil, soap and NaCl respectively. The standard experiment contained 1 N_w oil, 1 N_w soap but no NaCl. Normalities in excess of this are measured to the right and deficiencies to the left.

To apply the vertical correction a point is found on the graph where the E. M. F. is greater than the final equilibrium E. M. F. by an amount corresponding to a number in column 2. The corresponding number in column 4 is then the amount by which this point has to be lowered vertically to put it in its corrected position. The slope of the straight line so obtained is the rate constant of the reaction expressed in electrical units. It is seen from Figure 2 that a straight line does result from applying this correction and its slope; namely, 19.25 is the rate constant in millivolts per minute.

Experimental Results

Each experiment was carried out at least in duplicate and the results under favourable conditions usually agreed within a few per cent. In the case of some of the later experiments where salting out of the soap took place such close agreement was not possible owing to the thick consistency of the reaction mixture which rendered efficient stirring impossible.

The first series of experiments was carried out to test the effect of varying the amount of oil in the reaction mixture. In every case the oil was in sufficient excess for its influence to be constant during any one experiment. The results presented in Table II and Fig. 3 show that the rate constant is greatly dependent upon the first small portion of oil and that it becomes only slightly greater as the amount of oil is further increased. This is very different from the expectations of Treub (*loc. cit.*), but these actual experiments leave no doubt with regard to this result.

TABLE II (see Fig. 3)

Comparison of the rate of saponification of coconut oil when the concentrations of soap (made from coconut oil) and initial sodium hydroxide are kept constant but the volume of oil is varied.

Soap	Initial concentration of NaOH	Oil	(millivolt k minute units)
1.0N _w	0.1N _w	0.2N _w	5.58
"	"	0.5	5.53
"	"	1.0	6.0
"	"	2.0	8.0

In the second series of experiments the effect of increase of concentration of soap was similarly tested. It will be seen from the results in Table III and Fig. 3 that the increase in the rate constant is more rapid under these conditions than under any others studied.

TABLE III (see Fig. 3)

Comparison of the rate of saponification of coconut oil when the concentrations of oil and initial sodium hydroxide are kept constant but the concentration of coconut oil soap is varied.

Soap	Initial concentration of NaOH	Oil	(millivolt k minute units)
0.2N _w	0.1N _w	1.0N _w	0.75
0.41	"	"	1.13
1.0	"	"	6.0
2.0*	"	"	19.25

*This mixture was so viscous that difficulty was experienced with stirring.

Table IV gives the results of experiments to find the effect of adding glycerine to the initial reaction mixture. A large excess of glycerine lowers the rate constant. The effect however is small in comparison with the proportion of glycerine added. Presumably glycerine slightly diminishes the emulsifying power of soap because the latter is less colloidal in presence of glycerine.

TABLE IV

Comparison of the rate of saponification of coconut oil when the concentrations of oil, coconut oil soap, and the initial concentration of sodium hydroxide are kept constant but the concentration glycerine is varied.

Soap	Initial concentration of		Glycerine	(millivolt k minute units)
NaOH	Oil			
1.0N _w	0.1N _w	1.0N _w	—	6.0
"	"	"	1.0N _w	4.7

Table V gives the results of a comparison of the rate of saponification of coconut oil with that of trilaurin. Trilaurin is the chief constituent of coconut oil and, as would therefore be expected, the rate constants are very comparable.

TABLE V

Comparison of the rates of saponification of coconut oil, trilaurin, tripalmitin and tristearin

Oil	Soap	Initial concentration of		(millivolt k minute units)
	NaOH	Oil		
Coconut*	1.0N _w	0.1N _w	1.8N _w	6.7**
Trilaurin*	1.0	0.1	1.8	7.2
"	1.0	0.1	1.0	7.6†
Tripalmitin*	1.0	0.1	1.0	10.5
"	1.0	0.1	1.0	10.6†
Tristearin	1.0	0.1	1.0	15.3†

*These results are due to Miss Harrington.

**Interpolated.

†These results are due to A. V. Pitter.

It is seen from Pitter's results (comprising twenty experiments) that the rate of reaction rapidly increases in passing from trilaurin upwards in the homologous series, being doubled when tristearin is reached. This however does not necessarily mean that higher oils and fats are intrinsically more rapidly attacked but must be largely due to the simultaneous change in the soap present as emulsifying agent. In other words the highest soaps are the best soaps at high temperatures. A comprehensive series of experiments will be carried out in which the soap is kept constant and only the oil or fat varied.

In order to test if the size of the platinum electrode affected the results, an experiment was carried out with 1.0N_w coconut oil, 1.0N_w coconut oil soap and 0.1N_w sodium hydroxide using an electrode roughly 50% larger in area than that used in all other experiments. A rate constant of 5.7 was obtained instead of 6.0 (standard experiment).

In all the foregoing experiments two phases only were present during the whole of the reaction, aqueous phase and oil phase, these were maintained in intimate contact by the rapid stirring. In the following experiments salts was added at the commencement of the reaction, rendering the physical state of the mixture much more complex, and in many experiments the viscosity

was increased to such an extent that stirring was impossible. The results are collected in Table VI and VII and are graphed in Fig. 3. The physical state of the reaction mixture and the phases present are described in the last column of each table. The general form of the curve appears to be the same in the case of coconut oil and that of the very different oil, pure tripalmitin, but further experiments are required to confirm the exact shape of the curve.

TABLE VI* (see Fig. 3)

Comparison of the rate of saponification of tripalmitin when the concentrations of oil, sodium palmitate and the initial concentration of sodium hydroxide are kept constant but sodium chloride is added in increasing amounts.

Soap	Initial concentration of NaOH	Oil	Concn. of NaCl	k	Appearance of reaction mixture
1.0N _w	0.1N _w	1.0N _w	—	10.5	
"	"	"	0.5N _w	33.3	Homogeneous soap, high viscosity.
"	"	"	1.03	15.8	Heterogeneous soap.
"	"	"	1.25	39.5	" "

*These results are due to Miss Harrington.

TABLE VII (see Fig. 3)

Comparison of the rate of saponification of coconut oil when the concentrations of oil (1.0N_w) soap (1.0N_w) and the initial concentration of sodium hydroxide (0.1N_w) are kept constant but sodium chloride is added in increasing amounts.

Concn. of NaCl	k	Appearance of reaction mixture	Phases
—	6.0	Homogeneous soap solution.	
1.0N _w	11.1	Homogeneous soap solution oil in granules	Nigre only
1.5	14.5*	" " " "	" "
2.0	14.8	" " " "	" "
2.5	14.8	" " " "	" "
3.0	14	Heterogeneous soap, oil in granules.	" "
3.5	(12)	" " " "	Neat soap & lye
4.0**	(18)	" " " "	Curd and lye
5.0	(18)	" " " "	" " "
6.7 (satd.)	16.2	" " " "	" " "

*When 1.0N_w glycerine was present the rate was 12.4 instead of 14.5 thus confirming the result shown in Table IV above.

**It was found difficult to obtain reproducible results between concentrations of 3.0N_w and 5.0N_w sodium chloride, probably owing to the very complicated physical state of the reaction mixture.

Discussion of Results

The results given above are quite sufficient to illustrate that a quick and reliable method has been established for the comparative measurement of rate of saponification in heterogeneous reactions. Further, definite information has been gained with regard to the nature of the reaction.

It is evident from the results of Table II that doubling the amount of oil present does not double the rate constant as might have been expected. Thus we can conclude in accordance with the direct observations of Norris and McBain (*loc. cit.*) that a given amount of soap has a limited emulsifying action, since the surface of the oil evidently is not proportionately increased when the volume of oil is doubled. It was found that only a portion of the oil was emulsified, the remainder settling out immediately on standing.

This conclusion is supported by the results of Table III which show the effect of increasing the amount of initial soap. The rate constant is rapidly increased up to a concentration of $2N_w$ soap beyond which concentration the reaction mixture becomes so viscous that the experimental method breaks down. The only possible explanation of this increase in rate of reaction is that the oil is more perfectly emulsified when more initial soap is present. This is in accordance with observations of surface tension against oil which is indefinitely lowered as the concentration of soap is increased.

When we consider the results of Tables VI and VII from experiments where salt was added at the commencement of the reaction, the conclusions to be drawn are not quite so certain. It is well-known that soap boilers add solid sodium chloride to their reaction mixture during saponification in order to "salt out" the soap thus rendering the whole mass much less viscous and more manageable. Norris and McBain (*loc. cit.*) found that the presence of salt sometimes increased the rate of saponification and at other times decreased it according to the kind of oil used, the concentration of salt added and the physical state of the reaction mixture. However, no conclusions could be reached definite enough to enable them to predict the rate under any given set of initial conditions, owing firstly to their inadequate method of experimental procedure to which previous reference has been made, and secondly to the very limited amount of data then available with regard to the conditions governing the equilibria in the complicated ternary system soap: electrolyte: water. Since 1922 however our knowledge in this direction has been greatly increased. Phase rule diagrams for the systems sodium palmitate: sodium chloride: water,¹ potassium oleate: potassium chloride: water,² potassium laurate: potassium chloride: water,³ have been mapped out, and further, W. J. Elford, working on a semi-technical scale has proved conclusively that the equilibria occurring in a mixture of commercial oils with electrolytes, are exactly similar to those found in the systems of pure chemicals mentioned above.⁴

⁴ See Jerome Alexander's "Colloid Chemistry," Vol. I, Chap. V, by J. W. McBain.

In the light of this new knowledge it was determined to attempt to apply our new method of investigation of saponification to the systems resulting from the addition of sodium chloride to the mixture of oil, soap and aqueous alkali. From Fig. 1 of McBain and Langdon's paper (*loc. cit.*) we know that the addition of salt in increasing quantity to a homogeneous $0.5N_w$ solution of sodium palmitate at 90° produces no change in the homogeneity of the solution until a concentration of about $1.0N_w$ sodium chloride is reached. The solution then divides spontaneously into two (or possibly three) liquid layers (neat soap and nigre, or neat soap, nigre and lye). A further small increase in the concentration of salt suffices to convert this into two liquid layers, neat soap and lye. Miss Harrington when saponifying pure tripalmitin in presence of sodium palmitate and sodium chloride in this laboratory (see Table VI), chose her concentrations of salt so that the first and the third types of equilibria were represented. Her experiments were carried out in duplicate and the general form of the curve is that shown in Fig. 3. With the soap in homogeneous solution the rate constant is greatly increased by addition of salt. When sufficient salt has been added to produce neat soap: lye k is halved, but rapidly regains a higher value even within the neat soap: lye region.

The curve with coconut oil and coconut soap (Fig. 3) is the results of a more extensive series of experiments carried out by one of us (M. T.). Here again by utilising the unpublished diagram of W. J. Elford for coconut oil soap and sodium chloride it was possible to choose concentrations of salt which produced equilibria corresponding to those existing in the solutions of sodium palmitate: sodium chloride: water studied. With this oil also the rate constant increases while the soap and salt are in homogeneous solution and drops as soon as liquid layers are formed. Further addition of salt again increases the rate constant to above its previous maximum value and the high rate is maintained when the soap is grained out and the sodium chloride is added up to saturation.

The general conclusions to be drawn from the results so far obtained are reserved for a subsequent communication dealing with experiments in more concentrated solution.

Summary

1. A rapid and convenient method has been developed for the measurement of rate of saponification of oils by aqueous alkali whereby the influence of each factor can be isolated and measured independently. A very simple graphical method suffices to integrate the results.
2. The rate is in all cases proportional to the concentration of hydroxyl ions as measured by the hydrogen electrode.
3. The first small amount of oil greatly enhances the rate, probably because it is all emulsified, whereas further additions have a relatively slight effect.
4. The rate is more than proportional to the amount of soap in solution.

5. The effect of salt depends upon the physical state of the system but the fastest rates have been observed in presence of concentrations of sodium chloride approaching saturation.

6. Addition of glycerine slightly diminishes the rate.

7. Under comparable conditions tripalmitin is more rapidly saponified than coconut oil, in agreement with 3 and 4 above.

NEW BOOKS

International Critical Tables. Edited by E. W. Washburn. Vol. I. 28 × 22 cm; pp. xx + 415. New York and London: McGraw-Hill Book Company, 1926. Price: \$12.00.

"At the organization meeting of the International Union of Pure and Applied Chemistry, held in London in June 1919, the Union approved as one of its projects the compilation of International Critical Tables of Numerical Data of Physics, Chemistry, and Technology, and assigned to the United States of America the financial and editorial responsibility for the undertaking. The project was later given the patronage of the International Research Council at its Brussels meeting in 1923.

"On behalf of the National Academy of Sciences, the National Research Council of the United States accepted the executive, editorial and financial responsibilities of the project, and with the cooperation of the American Chemical Society and the American Physical Society, created a Board of Trustees to take charge of the financial and business administration, and a Board of Editors to supervise and carry out the preparation of the text.

"The first action of the Board of Editors, early in 1922, was to approve the appointment of Corresponding Editors in different parts of the world, particularly in all those countries in which conditions were such that they might be expected to take a really active part in the undertaking. In making these appointments, the Board first sought the advice of competent individuals in the several countries, and in accordance with the suggestions thus received, appointed ten Corresponding Editors and empowered them to arrange for Advisory Committees to assist in the work. In the case of certain countries, the Board was unsuccessful in its efforts to secure cooperation, usually either because of the receipt of no reply or an unfavorable reply, or through failure of the Corresponding Editor, after appointment, to perform his duties.

"The general plan of preparation of the Tables was as follows: The subject matter was first divided into some 300 different sections. The Corresponding Editors were then asked to recommend for the several sections one or more persons who should either have some special knowledge of the subject matter of the section, or be otherwise qualified to pass critical judgment upon the available information on the subject. On the basis of the recommendations thus received, the Board of Editors selected the Cooperating Experts, to whom was intrusted the task of critically compiling, and displaying in suitable form, the available quantitative information upon the several topics. In making these selections, the Board consistently endeavored to secure the best man *available* in the light of all the information which it possessed. In certain special fields composed of closely related topics, the Board provided also for the appointment of Special Editors to supervise the work and to assist in the final arrangement of the material."

In the first volume the material is presented under the general headings: national and local systems of weights and measures; symbols, basic constants, conversion data, dimensions, definitions; chemical elements and atoms; thermometry; laboratory methods for producing and maintaining constant temperatures; laboratory methods for maintaining constant humidity; barometry and manometry; psychrometry, density of moist air, change in barometric pressure with altitude; volume of liquid menisci; weights and weighing, calibration of volumetric vessels; standard buffer solutions and acid-base indicators; high vacuum technique; errors of observation; physical properties of chemical substances (including ready reference tables, crystal structure, disperse systems, sweetening agents, odoriferous agents); radioactivity; astronomical and geodetic data (including stars and nebulae, time, the solar system, composition of the atmosphere, the earth, gravity data); aerodynamics.

The ground covered is very much more extensive than that in Landolt and Börnstein's Tables; but the great merit of this work is that the data are to be presented critically, so that one at least knows which figure the sub-editor of any particular table considers the best. Of course, the sub-editor may be wrong; but he is better qualified to judge than all except a very few of the readers. Few things are more trying to the scientific man who is

not an expert, let us say on densities, than to find several widely differing densities for a given substance in Landolt and Börnstein, with nothing, except perhaps the date, to show which is probably the best.

It is a stupendous task which Dr. Washburn and his associates have undertaken because there are to be six of the volumes. So far as the reviewer is qualified to speak, this first volume is a great success and reflects credit on everybody connected with the work. It is a pleasure to learn that the advance subscriptions have exceeded all estimates. The scientific and technical public is more intelligent than we dared think.

Wilder D. Bancroft

Molybdenum, Cerium and Related Alloy Steels. By H. W. Gillett and E. L. Mack. 23 × 16 cm; pp. 299. New York: Chemical Catalog Company, 1925. Price: \$4.00. "This book is based on the thesis that a given alloy steel is a member of a class rather than a special entity and that with due regard to required heat-treatment it is often possible to produce, by combination or substitution of alloying elements, several chemically different steels which are practically interchangeable for the same engineering application.

"This idea has guided many metallurgists in recent years and has been emphasized well by Aitchison in his 'Engineering Steels.' Aitchison, however, has confined that book to the alloy steels universally available to the engineer. American conditions make it desirable that molybdenum steel also be discussed from this point of view. The United States has large reserve supplies of molybdenum while the domestic supply of many of the other alloying elements is restricted, either by Nature or by economic conditions. Molybdenum is now known to be one of the most potent alloying elements for steel. American steel makers know how to make molybdenum steel, and have made it readily obtainable in the American market.

"Molybdenum is destined to take its place beside nickel, chromium and vanadium as an alloying element. Before it can take and hold that place, its possibilities and limitations must be better understood, and it is for this better understanding that this book is written. The largest gaps in the knowledge of molybdenum steel seem to be its effect on the endurance and impact properties, and its effort on the properties of 'transverse' specimens. The experimental work herein recorded was planned with a view to filling those gaps. Since the experimental work on both molybdenum and cerium was carried on together, the title has been chosen to express this fact at the risk of erroneously seeming to class cerium as necessarily a true or a useful alloying element."

The chapters are entitled: the effect of alloying metals as a class; effect of alloying metals as individuals; interchangeability of alloying elements; molybdenum and cerium as alloying elements; the effect of molybdenum as shown by the transition points; importance of dynamic tests; tensile and impact test data for molybdenum and cerium steels; endurance tests of heat-treated molybdenum and cerium steels; normalized molybdenum steels; tests of longitudinal and transverse specimens; molybdenum, cerium, and zirconium in nickel-silicon steels; summary of the effect of molybdenum and cerium as alloying elements in steel.

"Pure iron is soft and ductile. It is classed with steel because of its chemistry rather than its strength. If no combination with iron were possible, the ferrous alloys would not have their dominant position and our minds would not make the automatic distinction between ferrous alloys as rather hard and rather strong, and non-ferrous as rather soft and weak. The addition of carbon to iron gives steel, a malleable alloy of iron and iron carbide," p. 17.

"An alloy steel is, broadly, one in which properties not attainable, or attainable with difficulty, in carbon steel are secured, or secured more readily by the addition of some other element or elements. The alloying elements strengthen the steel," p. 18.

"The comparison of alloy steels is made complex by the fact that no single property tells the whole story. Among steels similarly handled, i. e., by rolling and normalizing, by annealing, or by quenching and tempering, strength and ductility are inversely connected the stronger steels being the more brittle and the weaker the more ductile. In some cases, the maximum strength is the property more desired.

"When great ability to resist static distortion is required, the proportional limit is the property of greatest interest. When a machine part must resist repeated stress, the endurance limit is the most important one. If the design of the part calls for sharp changes of section or notches, like a screw thread, and the part may be subject to sudden blows, the ability to withstand impact is of importance.

"Some of these properties are inter-related, but seldom by straight-line relations. In going from the hard to the soft state in a given steel, the ductility and the resistance to impact increase more readily on the soft end of the curve; but on the very hard end, say above 200,000 pounds per square inch tensile strength, these properties may increase instead of continuing to decrease," p. 18.

"The latitude in heat-treatment conferred by alloy elements applies not only to the quenching or hardening operation, but to the tempering or softening operation as well. Alloy steels as a class resist tempering more than do the carbon steels. Not only do the former tend to harden more completely, but, if equally hardened specimens of the two classes are compared we find that the same draw temperature gives a softer and weaker product with the carbon steel than with the alloy steel.

"The resistance to tempering is usually great in those alloy steels, which show the greatest propensity toward hardening. While there may be no direct connection between the two phenomena, it nevertheless frequently happens that the steels containing enough of suitable alloying elements to make the austenite sluggish in breaking down into martensite are also sluggish in decomposing to secondary troostite and sorbite, and the sorbite especially is reluctant to soften further.

"According to Scott, silicon and chromium tend to make martensite delay its transformation to secondary troostite until higher temperatures are reached, as shown by heating of the hardened steels, while the other alloying elements do not change the transformation temperature. The troostite-sorbite change and the stages in the coarsening of sorbite cannot be followed by heating curves.

"This sluggishness towards tempering allows a good many alloy steels to be drawn for long times at relatively high temperatures without softening the steel unduly. But it is generally accepted that the release of internal stresses, set up in quenching, increases with increase in draw temperature as well as with time at a given temperature. Alloy steels may thus be made much freer from internal stress than carbon steels of equivalent physical properties.

"Not all the elements used for alloying with steel exert all the effects above noted, and the percentage of the various elements required to produce a certain result may vary widely. Nevertheless, the benefits conferred by most alloying elements are quite similar in nature, though varying in degree. It gives a very nearly correct view of the alloy steel situation to consider that, by suitable adjustment of the content of carbon, manganese, chromium, nickel, vanadium, molybdenum, etc., we can produce by proper heat-treatment an almost unbroken gradation of mechanical properties and engineering usefulness, ranging from an annealed low-carbon steel on one end to an air-hardened nickel-chromium-molybdenum-vanadium steel on the other. Even high-speed tool steel, though differentiated from the structural and automotive steels by the special carbides present, fits in on the end of the series," p. 26.

"Cerium appears to have no true alloying effect in steel and to do no good. Since it gives rise to inclusions, it probably does harm. There is a possibility that it might be used as a scavenger to eliminate or control sulfur if means could be found to eliminate the accompanying inclusions.

"Molybdenum is a very potent alloying element. Even small amounts greatly increase the propensity of steel toward hardening on quenching. This property is increased in the presence of other hardening elements. That is, molybdenum intensifies the hardening effect of other alloying elements.

"After hardening by quenching, the molybdenum steels require decidedly high draw temperatures to soften them to the same degree as other similar alloy steels. Heat-treated molybdenum steels of a given strength or hardness can therefore be produced by the choice

of a suitable composition of the steel as to molybdenum and other alloying elements, in which, by a long draw at a high temperature, quenching stresses can be largely relieved without softening the steel beyond the desired point. The ductility of the molybdenum steels at a given hardness, tensile strength, or elastic limit, is equal to that of any other and superior to most alloy steels. The great resistance to tempering makes the molybdenum steels attractive for use where strength at high temperatures is desired.

"When a very high tensile strength at ordinary temperatures is sought, molybdenum again offers a ready and certain means of attaining the result desired. For strengths which can be readily obtained by other heat-treated alloy steels, the use of molybdenum appears to allow as great a latitude in forging and quenching temperatures as is safe with any other alloy steels, and greater than is safe with some others.

"If a steel is to be used in the normalized condition, its molybdenum content should preferably be low. Steels in which the addition of molybdenum has produced a strong tendency toward air-hardening do not give very good results in the normalized state, unless a low proportional limit can be tolerated. In general, the molybdenum steels should be heat-treated to develop the best combination of properties.

"When heat-treated molybdenum steels are compared with other alloy steels on the basis of tensile strength or Brinell hardness, their behavior on repeated-impact or single notched-bar tests is the same as that of the others. The endurance properties of molybdenum steels, again compared with other alloy steels on the basis of strength or hardness, are substantially the same as those of other alloy steels.

"If the comparison is made on the basis of the same heat-treatment, especially at the same draw temperature, the molybdenum steels are stronger in endurance test and weaker in shock test; but this is because the molybdenum steels resist tempering more than the other steels and are therefore harder, stronger in tension, and less ductile. At a very high strength and hardness, the endurance properties of a molybdenum steel subjected to a long tempering process at a high temperature will probably be superior to those of other steels (which, in order to get this high strength, may only be tempered at much lower temperatures), because of the better release of quenching stresses. Within the machineable range this advantage is probably slight," p. 226.

"Properties similar to those obtained through the use of molybdenum can be obtained by various combinations of the other alloying elements, with suitable heat-treatment. However, the control of temperature in quenching and drawing, in order to obtain the desired results must, in general, be closer in the absence than in the presence of molybdenum. Uniformity of product will therefore generally be easier to maintain with the commercial molybdenum steels than with other alloy steels of the usual commercial composition.

"When the molybdenum content is very high, or when much molybdenum is added to a steel of the high nickel-chromium class, the control in drawing to a relatively low Brinell hardness would be less easy than without the molybdenum, while in drawing to a spring temper it would be easier. This is because the molybdenum increases the resistance to drawing so that the steel remains hard at high drawing temperatures, but when such a steel finally reaches the temperature at which softening begins, further increase in temperature hastens the softening at a high rate," p. 228.

There are five appendices: (A) composition, rolling, and heat-treatment of the experimental molybdenum and cerium steels; (B) test-pieces and methods of testing used, with special reference to endurance testing; (C) composition, rolling, heat-treatment, and test-pieces of experimental nickel-silicon steels; (D) finding list of references to sources of information on molybdenum steel, arranged according to the composition of the steel; (E) references to the literature.

This is an admirable monograph.

Wilder D. Bancroft

Introduction to Theoretical Physics. By Arthur Haas. Vol. II. Translated by T. Verschoyle. 22 × 14 cm; pp. + 414. New York: D. Van Nostrand Company, 1926. Price: \$6.00. The second volume is divided into three parts: atomic theory, theory of heat, and theory of relativity. Under atomic theory the chapters are entitled: the ele-

mentary quanta; theory of the hydrogen atom; Röntgen rays; theory of the elements; general theory of spectra and of atomic structure. Under theory of heat are two chapters, entitled statistics and thermodynamics. Under theory of relativity are also two chapters, entitled special theory of relativity and theory of gravitation.

"The problem of experimental Röntgen spectroscopy consists chiefly in the exact determinations of wave-lengths, both of absorption band heads and of individual emission lines. Much the most accurate method of measurement is the direct one based on Bragg's equation of crystal reflection, but this method can only be applied within a limited region of wave-lengths. The majority of wave-lengths are measured by means of a rock-salt or calcite crystal, which, as already mentioned in an earlier section, can be used for wave-lengths up to about 5,000 X. U. Wave-lengths more than twice as large can be reached with the help of selenite or mica, which have a larger lattice constant. Exact measurements by means of crystals have been perfected, principally by Siegbahn, to such a degree that, at the present time, Röntgen wave-lengths can be determined with an accuracy of about a millionth part of the measured value," p. 137.

"From the spectrum of the simplest of all atoms, hydrogen, it is clear that an electron revolving around the atomic nucleus can leave its usual orbit and revolve in an orbit of higher quantum number. Quite generally, we say that an atom is excited when one of its electrons describes an orbit other than its normal one, the electron then having a higher energy than usual. The excitation of an atom thus always demands an introduction of energy, while, on the return of the atom to its normal state, energy is liberated.

"As subsequent spectroscopic considerations will show, the multiplicity of higher levels, to which the electron can temporarily be raised, is very great. Each of these levels, however, which are not present in the normal atom and can only be realized when the atom is excited, is associated with a quite definite energy value, just as is the normal state. Hence, from amongst the manifold of excited states there must be one state that is distinguished by its having the smallest excess of energy over the normal energy value. This state is termed, in a narrower sense of the word, simply the excited state, and its surplus energy is called the excitation energy of the atom. It therefore represents the smallest quantity of energy which a normal atom of the element concerned can ever take up in connection with a change of its internal energy.

"The excitation of atoms is, of course, most readily effected with the most loosely bound electrons. These are obviously the peripheral electrons, which an atom loses when it enters into chemical combination as a positive ion, and which are therefore called the valency electrons. Since the elements in the first group of the periodic system are positively univalent, those in the second vertical column positively divalent, and so on, we must assume that the atoms of the elements in the first group each possess a single valency electron, those in the second group two valency electrons each, and so on.

"In general, changes in the orbit of the peripheral valency electron are probably responsible for those variations of the internal atomic energy which, in accordance with Bohr's frequency condition, manifest themselves in the optical spectra. For, in the optical region, a light-quantum is roughly a thousand times smaller than in the region of Röntgen rays so that optical lines can only be due to those electrons for which, because they are loosely bound, a change of orbit can be effected by a relatively small expenditure of energy. Moreover, it is easy to understand why the excitation of an atom should, in general, find expression only in the peripheral electrons, because it is only these electrons that, since they describe the highest-quantum orbits in the normal atom, will, on a transition to an orbit of still higher quantum number, find it unoccupied. An inner electron, on the other hand, must, on a transition to a higher-quantum orbit, generally find it already completely occupied (as follows from concepts of the grouping of electrons, to be discussed in greater detail later).

"We must assume that an excited state of the atom is not only abnormal, but also extremely unstable. After a very short sojourn, which we shall later find to be of the order of 10^{-8} sec., the return to the normal state takes place. Furthermore, provided the surplus energy is not changed into kinetic energy, this return is accompanied by the emission of a

light-quantum whose frequency, according to Bohr's condition, is equal to the quotient of the energy released and the elementary quantum of action. If the atom was not in the lowest of the excited states, but in one more highly excited, the return to the normal state may, of course, follow by steps, so that the emission spectrum then produced will contain lines for which both the initial and the final levels are possible only in an excited state.

"Conversely, the excitation of an atom, or its transformation from an already excited to a more highly excited state, can also be effected by the absorption of a light-quantum, provided the product of the frequency of the light-quantum and the elementary quantum of action be equal to the difference in energy between the actually existing and a higher-quantum state.

"A far more frequent way of exciting atoms than by absorption, however, is by supplying the requisite energy from the heat store of the body concerned. According to the fundamental concept of the kinetic theory of heat, incessant collisions occur in a gas between the rapidly moving molecules. By virtue of these collisions, energy of translation can of course be changed into intra-atomic energy, but when the atom struck was previously in the normal state, this can only happen if the relative kinetic is at least as large as the excitation energy. (In the monatomic vapours of the metals in the first two groups, which have been chiefly investigated, as well as in the rare gases, the concepts of atom and molecule are synonymous.) Now, when atoms thus excited by collision return to the normal state with the emission of light-quanta, the well-known phenomenon of thermoluminescence is observed. Moreover, the atoms of a gas can be excited, not only by sufficient heating, but also by collisions with rapidly moving ions in electrical fields, as is shown by the luminescence of rarefied gases in Geissler tubes," p. 146.

"Theory teaches us to expect that, when any vapour commences to glow with rising temperature, the first spectral line to be observed will be that corresponding to the transition from the lowest excited state to the normal state. The longer the wave-length of this line, the smaller will be the excitation energy, and the lower the temperature at which emission of the line will begin. As this temperature is exceeded, we must further expect that the transfer of translational energy will be sufficient to produce higher and higher excitations, so that new spectral lines will be continually appearing. In point of fact, all these theoretical conclusions are confirmed by experiment," p. 149.

"The earliest spark spectra to produce are those of the second group elements, a temperature of 2,000°C. being sufficient for this purpose, for their simple ions still contain one loosely bound electron. Arc and spark spectra of these elements are thus often to be observed together. On the other hand, it is extremely difficult to generate the spark spectra of the alkali metals, since their atoms in the neutral state only contain a single valency electron.

"These conclusions from Bohr's theory of the atom provide an explanation of several apparently paradoxical results in solar spectroscopy, as was first pointed out in 1920 by the Indian physicist, Saha. It had previously been quite inexplicable why sodium should appear very strongly in the solar spectrum, whereas potassium appears only weakly, and rubidium and caesium are entirely absent. According to Saha's striking explanation, the alkali metals are present in the sun, just as in the earth. To some extent, however, they remain unnoticeable, because, in consequence of the high temperature, they are almost invariably ionized, and their spark spectra, the lines of which lie in the ultra-violet, escape spectroscopic observation. That the arc lines of Na occur strongly in the solar spectrum, those of K only weakly, and those of Rb and Cs not at all, follows from the fact that Rb and Cs have the smallest ionization energies, K having a somewhat higher, and Na a considerably larger value. In contrast to the alkali metals, the alkaline earths are represented in the visible portion of the solar spectrum by the lines of their ionized atoms as well; for instance, the strong Fraunhofer lines *H* and *K* both belong to the spark spectrum of calcium.

"Moreover, Saha found in Bohr's theory a simple explanation for the remarkable fact that the heavier element calcium is to be observed in the spectrum of the sun's atmosphere at much greater heights than the much lighter element hydrogen. For the calcium lines lying in the visible region of wave-lengths require a smaller excitation energy than the

hydrogen lines lying in the same region; the hydrogen lines which are readily excited belong to the ultra-violet. In the higher regions of the sun's atmosphere, where the temperature is less than in the lower regions, the energy transferred by molecular collisions therefore suffices to excite the visible calcium lines, but not the visible hydrogen lines," p. 151.

"The radiation emitted by a body whose atoms are excited by primary rays is called fluorescent radiation. In the special case in which the wave-lengths of the secondary and the primary radiation are identical, we speak of a resonance radiation. According to the discussion in a previous section, we may expect to meet with such radiation when light of the wave-length of a resonance line of an element passes through the vapour of the element at a temperature below that at which any of the atoms are excited.

"The phenomenon of resonance radiation was discovered and investigated long before the atomic theory was established, first by Wood in the case of *mercury*, and subsequently by Dunoyer, Wood, and Strutt in the case of alkali metal vapours, especially sodium vapour. At low pressures, the total energy of the re-emitted light does, in fact, agree with the energy absorbed from the primary radiation. It is only when the pressure is increased that a part of the absorbed primary radiation is changed into molecular energy of translation, with a resulting heating of the fluorescent vapour.

"When a gas is irradiated with light of a frequency greater than the resonance frequency and corresponding to the difference in energy between the normal state and a higher, excited state, the return of the atom from this more highly excited state may take place in steps. In the fluorescent radiation, therefore, lines of greater wave-length than that of the exciting light may occur. Under no circumstances, however, can an atom which, before excitation, is in the normal state, emit fluorescent radiation of shorter wave-length than the primary radiation, and in this lies the explanation of Stokes's rule of fluorescence, which was mentioned in an earlier section. Only when the irradiated atom has been previously excited can it happen, by way of exception (*e. g.*, on a return to the normal state), that the wave-length of the fluorescent radiation may be shorter than that of the exciting radiation," p. 176.

"For many elements, it has been possible to make direct experimental determinations of the excitation potential by purely electrical methods. Using suitable apparatus, the electrons are made to pass through the gas or vapour, and the resulting current is measured with a galvanometer, while the applied potential difference is also observed. If the current be plotted on a graph against the potential, the curve exhibits a strongly marked discontinuity for the potential at which inelastic impacts first occur. With many elements, the first flashing out of the resonance line caused by the electronic collisions could be observed at this potential, and this in itself must be regarded as a brilliant experimental confirmation of Bohr's frequency condition.

"From the point of view of Bohr's theory, further discontinuities in the current are to be expected for values of the potential which, when multiplied by the elementary quantum of electricity, give the energy difference between the fundamental state and a state excited to a higher degree. The determination of these closely adjacent potential values, however, generally meets with experimental difficulties, and has hitherto only been successful in the case of mercury. On the other hand, the potential at which the electron impacts first produce ionization of the atoms of the gas can be fairly sharply determined for many elements. This potential is called the ionization potential. It must be equivalent to the fundamental term of the atom, inasmuch as this corresponds to the work necessary for the removal of the electron concerned from the atom. The ionization potential must therefore satisfy eqn. (1) for a wave-length corresponding to the fundamental term," p. 181.

"Like the phenomena of fluorescence, photochemical reactions can also be "sensitized." That is to say, under certain circumstances the reactions can also be produced by light of wave-lengths which are not absorbed by the reacting molecules, provided only that a sensitizer which can absorb the light be added. Owing, presumably, to molecular collisions, the surplus energy absorbed is transferred from this sensitizer to the molecules of the substances concerned, which can then react. This appears especially clearly from an experiment of Franck and Caro, in which mercury vapour served as sensitizer for the dissociation

of hydrogen. It is known from thermochemical measurements that the energy required for the resolution of a molecule of hydrogen into its two atoms amounts to about 6×10^{-12} ergs. Dividing this by the elementary quantum of action, we obtain, a frequency of about 9×10^{14} sec.⁻¹, or a wave-length of approximately 3,000 Å.U. A non-excited hydrogen atom, however, cannot absorb any radiation of greater wave-length than its resonance line, which (as the first line of the Lyman series) lies at 1,216 Å.U., far in the ultra-violet. Franck and Cario introduced mercury vapour into the hydrogen, and submitted the mixture at sufficiently low temperature to the action of the rays of 2,537 Å.U. wave-length emitted by a quartz mercury lamp. Although, in accordance with what we have just said, these rays could not be absorbed by the hydrogen, yet a dissociation of the hydrogen took place. This was clearly proved by a reduction of metallic oxides which, as is known from experience, can only be effected at the temperature in question by monatomic, but not by diatomic, hydrogen. For the rest, the best-known instance of a photochemical sensitization is afforded by the sensitization of a photographic plate with suitable dyes which possess in the red the absorption lines lacking, in that region, in the silver halides.

"The converse of photochemical processes is represented by chemico-luminescence, due to a transformation of chemical energy into light-quanta. A well-known example of this is the oxidation of aldehydes at low temperatures, which is accompanied by an intensive luminescence. Haber and Zisch have shown that, on leading a stream of chlorine through sodium vapour, chemico-luminescence ensues; it can be recognized by the appearance of the characteristic D-lines of sodium at a temperature at which a luminescence due to heat is obviously excluded.

"Chemical reactions may be produced not only by the absorption of light-quanta, but also by electron collisions. The experimental investigation of these processes promises to be of great importance, because it permits of an exact determination of the minimum energy requisite for the initiation of a chemical reaction," p. 191.

"In the light of modern atomic theory, Dulong and Petit's Law appears simply as a special case of a more general expression for the atomic heat, which is approximately represented by eqn. (3). This equation was derived in 1907 by Einstein, and formed the first application of the quantum principle to mechanical oscillations. Exact determinations carried out by Nernst and other investigators subsequently to the formulation of Einstein's law have shown, in fact, that the atomic heats of all substances converge at sufficiently high temperatures towards $3R$ and, at sufficiently low temperatures towards zero. The atomic heat of diamond (C_V) at about 1,000°C. amounts to 5.5 cal. On the other hand, the atomic heat of copper, for example, falls to 3.38 at 88° K., to 0.54 at 33° K., and to 0.22 cal at 23° K. The decrease is certainly most marked with diamond. At 86° K. the atomic heat is but 0.03 cal., and at 23° K. it was found by measurement to be 0.00 cal.; i. e., at these low temperatures the idea of temperature is practically meaningless in the case of diamond," p. 281.

The student will have difficulty with the discussion of the theory of gravitation. It is perfectly true that we shall get the same apparent effect with an observer moving at a constant rate and a particle undergoing uniform acceleration or with an observer undergoing uniform acceleration and a particle moving at a constant rate; but that merely indicates that there are two ways of considering a homogeneous gravitational field, p. 336. The important thing is the calculation made by Einstein. This is given on p. 370; but not in a form or with an emphasis which will overcome the false impression produced by the preceding pages. For pedagogical effect, a reference to it should have been made on p. 337.

Wilder D. Bancroft

Chemistry in the World's Work. By Harrison E. Howe. 22 × 15 cm; pp. vii × 244. New York: D. Van Nostrand Company, 1926. Price: \$3.00. "The object of this work is to emphasize, in language easily understood by those not technically trained, the part which chemistry has played in assisting in the attainment of our present level of civilization." The chapters are entitled: solitude; mental isolation; allies of the sun; food and famine; contributions of chemistry to cloth and clothing; decoration—escape from monotony;

metals, the master; materials of construction; permanency of possessions; health and sanitation; power; abolition of drudgery; chemistry in national defense; chemistry, a tool; analysis and synthesis; the trend and purpose of modern research.

The following quotations will give some idea of the scope and quality of the work. "Chemistry has also contributed to the safety of transportation. The materials supplying the light in the lighthouses are made under chemical control. The powerful lenses also come from the chemist's workshop, and the small gas buoys are his product. An interesting example is the red lens universally used as a danger signal on railways. Before the chemist had shown how to make a glass which is called spectroscopic red, the lenses having a red appearance did not always transmit a red light. By the use of selenium and some other materials it was shown that a glass could be made which would always transmit red light even when submitted to a severe spectroscopic test. Previously there had been cases where engineers undergoing a periodic test for color blindness might, due to some imperfection of the sight, see from the same lens red and green alternately, depending upon the distance they chanced to be from the light. With a spectroscopic red lens, we may be sure that red light will be transmitted, and if any other color is reported to be seen, we may be sure the fault lies wholly with the observer and not with the lens," p. 6.

"Casinghead gas is that which accumulates in the petroleum wells and at one time was allowed to waste. This is now condensed, blended, and made available by the hundreds of millions of gallons. Then a chemist found that one essential difference between natural gases was the percentage of wet gas later identified as something recoverable as gasoline. Those vapors are collected in oil from which the gasoline is distilled, or, since our wartime defense against poisonous gases has taught us so much of activated charcoal, this form of carbon is used as an absorbent for these gasoline vapors," p. 11.

"No balloon fabric has yet been found through which air will not diffuse, thus diluting the gas and diminishing its lifting power. Pure gas has a considerably greater lifting power than gas mixed with air. Hydrogen, though cheap to make, cannot be purified following contamination due to air leaking into the gas bags. It is therefore changed some fifteen times a year. Helium can be purified at low cost and re-used. This constitutes an advantage which greatly offsets any original difference in the first cost of the two gases. Indeed, the net cost of helium under the most modern conditions of operation and purification is no greater than hydrogen," p. 19.

"A stone cast into still water gives rise to a series of ripples most pronounced near where the stone struck and fading away as the distance from this point increases. If stone after stone could be thrown in exactly the same spot, ripples of a given magnitude might be maintained and the finer ones might even reach an increased distance from the center. If there were some way of introducing more energy into the feeble waves distant from the center, these outermost waves might be increased in size to compare with those near the source of the impulse. Roughly speaking, what has been done in long distance telephony is to supply energy to these waves, that they may be kept at the strength of the initial impulse. This method of attacking the long distance problem made every instrument a long distance telephone, and even the rural telephone is found unsatisfactory only when all the other subscribers on the party line insist on taking down the receivers when they hear a call, that nothing in the way of news or gossip may escape them. This practice diverts so much energy that the original parties to the conversation have an insufficient supply left them," p. 31.

"A variety of chemical compounds have been used in sound-reproducing devices; but the most rugged, permanent, and withal satisfactory record has been of the synthetic resin type. It has been the chemist's major contribution to this art," p. 35.

"To-day, acetylene is so universally available in compressed form, another chemical achievement, that there seems no need for any difficulty in its production and use. Just as the mariner is often protected by the flashes of acetylene gas in the gas buoy off shore, so also is the motorist warned on the country highway and in the cities of crossings or danger ahead. A gas accumulator, using acetylene, is the active principle of these highway lighthouses, which flash their warning at regular intervals," p. 47.

"The chemist has helped the animal husbandman to establish important facts with relation to stock feeding. It has been shown that the calcium so important in our diet and largely derived from milk is taken from the skeleton of the cow; hence our interest in learning how to make available through the diet other calcium to keep the animal in healthy condition. The race horses of Kentucky are noted the world over and the blue grass of Kentucky contains a larger quantity of available calcium to strengthen the skeleton of the horse than is commonly found elsewhere. Chemistry has also helped to establish some important economic facts in animal feeding, for it has been shown that there comes a time when a steer literally eats his head off, for without change in feed he proceeds to replace with water a part of the fat previously accumulated at no little expense to its owner. Just as traces of elements are important in the soil, so also they are important in animal metabolism, though the full story is not yet known. The chemist has helped to make a promising start on the chemistry of the ductless glands, and the active principles of some of these have already been synthesized. Enthusiasts predict that with a more complete knowledge of the chemistry of these glands will come the ability not only to control growth, but in the case of the human being to influence mental development as well and perhaps control sex. Indeed, if the prediction of these workers should come true, the power conferred through this work might be greater than the race could properly administer," p. 62.

"A chemical study of the diet of various tribes and peoples serves to explain conditions otherwise mysterious, and if the prejudices and fastidiousness of some peoples can be overcome, this information should be helpful in planning a rational, economical diet. Many have pitied the oriental with his monotonous diet of fish, soya or mong beans, and rice; yet the laborer of the Orient performs a prodigious amount of work on a diet which seems starvation rations to the occidental. One difference has been found to lie in the soya or mong bean as compared with the American Navy bean. The former in the digestive tract produces the types of amino acids of the greatest help to the body, while the Navy bean does not," p. 65.

"How fortunate is the closer cooperation between chemistry and medicine may be emphasized by the delays which accompanied the adoption by the physician of some of the earlier contributions of chemistry. Ether was not recognized as an anaesthetic until 1846, though the compound had been discovered more than five hundred years before, and in that interval unnumbered thousands suffered agony because its ability to produce insensitiveness to pain was not known. Two hundred years elapsed after the discovery of magnesium sulphate by the chemist before the physician learned that it would give great relief in the case of burns, strychnine poisoning, and lockjaw. These are but two of many such instances not likely to recur under modern conditions," p. 147.

"Calcium has also been found indispensable both in the metabolism of man and the domestic animals, and the problem here seems to be how effectively to introduce calcium and have it assimilated. One specialist in hay fever and similar ailments maintains that those having a deficiency of calcium in the blood are the greatest sufferers and adds to his credit cases of relief following the injection of soluble calcium salts into the blood stream," p. 155.

"Sewage disposal has a direct relation to water supply, since improperly treated sewage of one town or of one house may contaminate the water supply of its neighbor. Filtration, sedimentation, and the activity of one or another type of bacteria are usually depended upon to render sewage effluent innocuous. Filter beds from which the sediment may be collected for further disposal are often used. The Imhoff tank has many installations, and of late years the importance of activated sludge, a process where the work of the bacteria is furthered by stirring the sludge with air currents, has won its adherents. Occasionally the plan adopted makes necessary a filtration of the treated sewage, and, as the engineers of the Milwaukee sewage disposal plant found out, this may involve chemistry. It was only after local chemists showed that the hydrogen ion concentration must be adjusted and the temperature controlled that it was found possible to filter the sludge at all, and but for the application of this knowledge an elaborately designed and expensive plant might have failed of its purpose," p. 160.

"At least one plant in the United States is giving a thorough test to the mercury boiler, a plan which seeks to take advantage not only of the greater heat which the mercury vapor can carry, but the use of the superheated vapor in a turbine, after which the heat is given up to water for the formation of steam, the combined steps giving a much increased return for the fuel consumed. Experiments have also been conducted with diphenyl ether and with sulfur dioxide as the medium along the same lines," p. 176.

"Dr. W. R. Whitney, in his Los Angeles address before the American Chemical Society, said that if all the electrons, now believed to be the ultimate particles of matter, in a drop of water could be enlarged until each of them became as big as the original drop of water they would form a layer three feet deep entirely covering the earth. The molecules are so small that if a glass of water were thoroughly stirred with all the water in the earth and in the sea, and a second glass filled with a mixture, it would contain two thousand of the original molecules," p. 220.

"Our day is unique in the extent to which scientists are cultivating the borderlands between the major divisions of science. Excellent and well known examples are to be found in geophysics, astrophysics, and biophysics. Physical chemistry developed rapidly as a specialty and has grown in importance until it bids fair to dominate the entire chemical field. Its laws and theories are being everywhere applied. Methods peculiar to physical chemistry find a place in all research laboratories, and many of our most remarkable recent achievements in industry must be credited to men well grounded in its principles. Biochemistry affords opportunities unsurpassed by any science and worthy of any genius, dealing as it does with the most complex substances; the problem is further complicated in that reactions must be interpreted almost in terms of life itself," p. 225.

It is quite remarkable that the author should be able to write such a book as this in his stride, as it were. This had to be done in odd moments and not many of them.

Wilder D. Bancroft

Physikalische Chemie der Zelle und Gewebe. By Rudolf Höber. Sixth edition. 23 × 16 cm: pp. xvi + 955. Leipzig: Wilhelm Engelmann, 1926. Price: 39 marks paper; 42 marks bound. The fifth edition was reviewed a few years ago (27, 692; 28, 1331). There are many interesting things in the new edition. It is now believed that the high concentrations of sodium urate are due to supersaturation and not to a colloidal solution, p. 67. In an acidified albumin solution which has a pH of 2.49 as determined by the hydrogen electrode, methyl violet gives an apparent value of 2.53, which is not bad; but the pH as determined by means of Congo red is 5.30, p. 91. On p. 135 is the statement that equal weights of palladium foil, sponge, and black take up equal volumes of hydrogen, from which Höber deduces that the hydrogen is in true solution. The figures, as the reviewer knows them are that palladium foil takes up about 900 volumes of hydrogen and colloidal palladium about 3000.

Höber points out, p. 145, that an acid dye is taken up by wool more strongly from an acid solution than from an alkaline solution, while the reverse is true of basic dyes. He is also clear that sodium sulphate will tend to strip an acid dye from wool and will tend to force a basic dye on wool; he has not mastered the theory of substantive dyes. He quotes Svedberg, p. 167, to the effect that when colloidal ferric oxide is made finer and finer, the color approaches more and more that of a solution of ferric oxide. It does not do this at all, a very fine suspension of ferric oxide being practically as colorless as water. Höber does not explain how sodium oleate carries haemoglobin through an ultra-filter, p. 171; but it seems probable that this is a case of peptization. The author has apparently not heard of McBain's theory of the colloidal ion or micelle and consequently he has some trouble with Congo pure blue, p. 212, and with the sodium salt of thymonucleic acid, p. 213.

Gelatine is more readily precipitated by alcohol when a mixture of sodium and calcium chlorides are present, than when either of these two salts is present by itself, p. 240. Höber considers, p. 242, that we get the most marked antagonism between ions when the colloid is on the dividing line between a suspension colloid and a hydrophile colloid. On p. 249 the author says that the solubility of difficulty soluble calcium salts (such as calcium sulphate, phosphate, and carbonate) is increased very much by gelatine and enormously by serum.

In the next line it appears that he means the concentration of the suspended material and not the solubility. On p. 250 we learn that sodium chloride diffuses faster in a gelatine jelly than sodium bromide while sodium bromide diffuses faster than sodium iodide. This is very important, if true, and should be checked.

The rate at which camphocarbonic acid decomposes into camphor and carbon dioxide varies in the ratio of 1:15 as one passes from water to aniline as solvent, p. 277. These solvents can be considered as catalytic agents. In laevo-rotary nicotine as solvent the dextro-rotary camphoric acid decomposes more rapidly than the laevo-rotary acid. The author does not agree with Armstrong's formulation, p. 283, that an enzyme builds up the biose which it cannot decompose and decomposes the biose which it cannot build up.

On p. 294 the author calls attention to the well-known facts that stannic chloride and ferric chloride cause exclusively chlorine substitution with benzene, while light causes exclusively addition of chlorine, and iodine monochloride comes in between. He compares this with copper splitting isobutyl alcohol into the corresponding aldehyde and hydrogen, while alumina causes decomposition into isobutylene and water. This again is paralleled by the different actions of pepsin and trypsin on albumin. While Rosenthal succeeded in decomposing starch with frequencies of 440-480 and albumin with frequencies of 320-360, p. 297, the author refuses to accept Rosenthal's hypothesis that enzymes act by setting up definite frequencies.

Very interesting is the observation, p. 305, that the rate of oxidation of oxalic acid in presence of charcoal decreases with increasing concentration of oxalic acid, because the oxalic acid decreases the adsorption of oxygen so much. In some cases involving enzymes, p. 320, the relative reaction velocity is smaller the higher the initial concentration.

Human blood freezes at -0.56° to -0.58° . The blood of all the other mammals freezes at -0.58° , which corresponds, at the normal body temperature, to an osmotic pressure of about eight atmospheres, p. 334. The constancy of the freezing-point is regulated by the kidneys since the osmotic pressure of the urine may easily vary between twelve and twenty-six atmospheres in the course of twenty-four hours. The physiological saline solution for mammals is one percent sodium chloride. The 0.6 percent one is right for frogs which have an osmotic pressure of only four to five atmospheres in the blood, p. 336.

As an instance of indicator errors due to adsorption, Hober cites the case of living muscles p. 381, which were put in a buffer solution of $\text{pH} = 7.82$ and in one of $\text{pH} = 5.2$. The first buffer solution is colored blue by bromthymol blue and the second yellow; but, in both cases, the muscles were colored yellow on additions of crystals of the indicator. Sea water is apparently more alkaline than the blood, p. 383; but there is some question whether the body liquid of sea organisms has exactly the same acidity as the water itself.

Jacques Loeb was able to produce parthenogenetic development by means of hypertonic sea water at Wood's Hole, p. 384, while the experiment failed in California. The reason for this was found to be a difference of alkalinity between the waters of the Atlantic and Pacific Oceans at the two laboratories. The experiments succeeded when 0.0002 mols NaOH was added per liter to the California sea water. Living cherries and red beets do not color water; but if they are killed by heat, the dye is said to come out, p. 403. Hober assumes that this is not a rupture of the cells due to the heating; but is a permanent change in the permeability of the cell membrane. If this is true, it should be possible to produce the same change by suitable additions to the water and it is very desirable that this should be tried. It might easily be possible that one could show reversible permeability with the living beet in this way.

"Some pollens explode and scatter their contents when placed in water because the cell wall cannot withstand the great osmotic pressure. This pressure phenomenon can be shown in a striking way by growing fungi such as *Aspergillus niger* or *Penicillium glaucum* in a concentrated potassium nitrate solution. The cell content increases gradually up to an osmotic pressure of over two hundred atmospheres. If these modified fungi are then brought into pure water, the cell walls are scattered with great force by the colossal pressure set up," p. 413.

Hamburger's method with blood corpuscles does not give real osmotic pressures because different results are obtained with blood from different animals although there are no such differences in the bloods. What happens is that, for each kind of blood, the outflow of the coloring matter is a function of the osmotic pressure, the different membranes breaking down at different pressures, p. 420. The method is apparently satisfactory for determining isotonic solutions.

Osterhout's data for the cell concentrations of *Valonia* with reference to the outside concentrations are quite extraordinary, p. 454.

	Cl	SO ₄	Na	K	Ca
inside	1	1	1	40	1
outside	1	7.1	5.1	1	7

The most natural explanation would be that the ions are not present as such; but that seems to be barred out by the high conductivity. If the cell is permeable to water, as is apparently the case, there must be a specific pumping action going on. This is not impossible because we have this in the case of the frog, whose skin is permeable to water and who would burst if the incoming water were not removed through the kidneys, p. 422. It is also interesting to note "that among men we find blood corpuscles containing no sugar although they are in a plasma containing sugar; in other cases the sugar content inside is larger than outside. In some cases of glycaemia, there is relatively little sugar in the plasma and in other cases there is relatively a good deal in the blood corpuscles," p. 465. Although the freezing-points of the blood of different mammals is fairly constant, the composition varies considerably, the potassium content being high and the sodium content being low for the horse, the pig, and the rabbit, while the reverse is true for the ox, the sheep, the dog, and the cat, p. 474.

In the muscles of the frog there is much more potassium than sodium while the reverse is true for the serum, p. 489. On leaching the muscles with sugar solution, the percentage loss (not the absolute loss) of sodium was much greater than that of sodium. This is explained most easily on the assumption of greater adsorption of potassium than of sodium. The experiments on the conductivity indicate that much of the salt is present in a non-conducting form. The laming of muscles by cane sugar solution is believed by Overton to be due to the extraction of sodium.

By impregnating collodion membranes with definite amounts of lecithin, cholesterolin, and castor oil, Thieulin has made them impermeable to inorganic salts but permeable to chloral hydrate, cocaine, the salts of the alkaloids, and weak organic acids, p. 513.

"Loewe studied the distribution of methylene blue between water and chloroform in which lecithin, cephalin, or some other lipid had been dissolved. At low concentrations the distribution was more in favor of the organic solvent than at higher concentrations. Loewe explained this by assuming that the lipoids were in colloidal solution in the chloroform and the dye was adsorbed on the surfaces of the lipid particles. Freundlich and Gann proved the correctness of this assumption. They found that the distribution of methylene blue was described very accurately by the adsorption isotherm and they considered that the lipoids carried some water into the chloroform, producing there a disperse phase which adsorbed the methylene blue.

"Chemical factors may also play a part. Freundlich and Gann found that chloroform does not itself dissolve methylene blue and does not after addition of neutral fats. When the fats are somewhat decomposed and therefore contain fatty acids, the chloroform-fats take up methylene blue and other basic dyes but not acid dyes. Nirenstein has shown that addition of an organic base gives to a neutral organic solvent, such as oil, the power of taking up acid dyes," p. 509.

Traube and Kohler have shown that narcotics tend to peptize gelatine and consequently to prevent the setting to a jelly, p. 593. This should be studied to see whether this is a peptization due to adsorption, or whether it is a case of the displacement of the water equilibrium. If it is the latter, one ought to have the same narcotics acting like potassium iodide in other cases.

Höber calls *Fundulus* a fish in one place and a sea anemone in another, which is confusing to the chemist. In addition to the calcium-sodium antagonism, there is also a potassium-sodium antagonism. The poisoning action of potassium chloride is increased by addition of sodium chloride until the ratio of potassium is about 1:10. Further addition of sodium chloride decreases the toxic action until an optimum is reached at a ratio of about 1:17. Further addition of sodium chloride causes an increase in toxicity, which is probably due to the sodium ion, p. 682.

Wilder D. Bancroft

Applied Colloid Chemistry. By Wilder D. Bancroft. Second edition. 21 × 15 cm; pp. ix + 489. New York: McGraw-Hill Book Company, 1926. Price: \$4 00. "Much water," as the author states, "has flowed through the colloid mill in the last five years," and the record of its flow contained in this new and enlarged edition of the much-prized book by Bancroft, will be greatly welcomed by all those who are familiar with the former edition of the work and by many new readers whom this discussion of Colloid Chemistry will undoubtedly and deservedly attract.

While the general arrangement of the subject matter has been found satisfactory and remains unchanged, the growth of knowledge has led to the subdivision of certain chapters, so that separate chapters are now devoted to chemical reactions in which adsorption plays a part (contact catalysis), the electrical properties of colloids, the stability of colloidal solutions, fog, and smoke; and the book as a whole has been enlarged by over 140 pages, giving a concise, clear and comprehensive survey of the whole field of colloid chemistry.

This is a great work and original in its treatment. Although the book can be opened at any page and read with pleasure and profit, it is not a book for a lazy or relaxed mind. As one reads, all one's faculties must be kept alert, for one is borne forward irresistibly not as a smoothly flowing stream but as by a great and turbulent river, with here and there great rapids where one is buffeted by facts, now on this side, now on that; and sometimes brought up sharply by real or apparent contradictions. Not for a moment, however, is the interest allowed to droop as the author enumerates, example after example, the varied applications of colloid chemical principles in the arts and industries as well as in the home. As one reads one cannot but marvel at the obvious extent of the author's knowledge, his critical and sound judgment, and the ability with which the great wealth of facts is sifted and arranged. As in all really great and original works, the author's personality, genial and compelling, shines through every page, lighting up the facts with rose-hued flashes of humor and infusing them with a strong human interest. See, also, how in discussing the blue of turbid media, the artist comes out in the quotation from Bruce's "Assault on Mount Everest": "the blue haze of the monsoon converts the distant shadows from their crude purple-brown to the most magnificent and sometimes brilliant blue. Once or twice one looked in vain on one's palette for a blue of sufficient brilliance and intensity to reproduce the colour of the shadow twenty or thirty miles away."

With the large number of experimental results to which reference is made the reviewer often desired more tables of numerical data, but the insertion of these would doubtless have disturbed the general flow of the discussion, and since full bibliographical references are given, the data can readily be obtained.

The author, being human, has like other fallible mortals allowed a small number of misprints to remain in the text, but they are easily recognised for what they are. But why does he lapse from the pure latinity of univalent and bivalent to the hybridism of trivalent and tetravalent? Is it not also a mistake to say that "Graham suggested calling them colloids, from the French word for glue"? Graham, in his original paper, certainly does not state the derivation of the term colloid which he introduced, but surely we can be certain that one who in the same communication introduces the term pectous, and gives, in a footnote, the Greek adjective from which he formed it, did not go to French for the origin of the term colloid. The student of colloids, however, will probably regard this matter as one "ganzlicher Wurstigkeit", and rightly see in it the tiny pebble thrown by the reviewer to

cause a ripple on the deep pool of grateful appreciation. With or without the recommendation of the reviewer this book will be read by every one who takes an interest in colloid chemistry and its applications; the reviewer has the task merely of announcing its appearance.

Alex. Findlay

Alcoholic Fermentation. By Arthur Harden. Third edition. 24×17 cm; pp. 194. London and New York: Longmans, Green and Co., 1923. Price: \$2.00. The second edition was reviewed six years ago (25, 264). The order of presentation has been changed a little, the chapter entitled carboxylase now coming immediately after the one on the coenzyme of yeast-juice. There is only one new chapter, the reducing enzyme of yeast.

"That the reducing properties of yeast are certainly due, at all events in large part, to an enzyme was shown by Hahn (1903), who found that yeast-juice reduced methylene blue but lost this property almost entirely when heated. Dried yeast and zymin (yeast treated with acetone) also reduced methylene blue, but more slowly than yeast-juice," p. 79. Yeast and its preparations are now known to bring about a very large number of reductions. "The reductions in all these cases are carried out by adding the substance to be reduced to a fermenting mixture of 10% cane sugar solution and 10% of living yeast, and it is sometimes necessary to add a further amount of yeast and sugar to complete the reduction. Thus the reduction of aldol was effected by gradually adding 50 g. of aldol to a mixture of 250 g. bottom yeast with 25 litres of water and 250 g. cane sugar, two additional amounts of 100 g. yeast and one of 200 g. together with some water being added before the sugar had all disappeared. Two similar fermentations were carried out simultaneously and after 7 days 65 g. of 1,3-butylene glycol were obtained from the 100 g. of aldol used i. e. 63.5% of the theoretically possible amount. This glycol was optically active, $a = +10.9^\circ$ ($l = 1$).

"This particular experiment well illustrates two striking features of these reductions.

1. The yield is frequently more than 50% of the theoretical amount, being in some cases as high as 80%. This affords definite proof that the alcohol is not produced from the aldehyde by Cannizzaro's reaction:

"Further proof is afforded by the fact that the corresponding acid is not formed.

2. The product of reaction, when its constitution admits of it, is often optically active, showing that the reduction is carried out by an asymmetric agent and is therefore, probably a true enzyme reaction.

"Nearly all these reductions have been effected in the foregoing way, but the addition of sugar is not always essential. Thus a yield of over 50% of butylene glycol was obtained from aldol by the action of a total of 1550 g. of yeast during two months on 100 g. aldol without any addition of sugar. It must be remembered, however, that this quantity of yeast might contain a large proportion of glycogen (10-30%) which would gradually undergo autofermentation," p. 81.

"It may be regarded as established that the source of the hydrogen used up in the various reductions described above is either water (Bach), in which case some acceptor for the oxygen must also be present, or an oxidisable substance, which is directly capable of losing hydrogen (Wieland) and thus acts as a hydrogen donor, and great interest attaches to the nature of his compound.

"Some light is thrown on this problem by the experiments of Harden and Norris who showed that dried yeast and zymin lost the power or reducing methylene blue when they were thoroughly washed, but that this power was restored by the addition of the washings, of ordinary bouillon (peptone-beef-broth) and of various aldehydes, but not of formaldehyde or acetaldehyde. It is to be presumed that the active substances, which restored the power of reduction, were capable of acting as oxygen acceptors (or hydrogen donors) and thus enabled the "hydrolytic oxidation-reduction" to proceed. The reaction is evidently highly specific, as many easily oxidisable substances were inactive, including formaldehyde, which acts as the oxygen acceptor in Schardinger's reaction in milk.

"These experiments, however, do not indicate what is the actual substance which undergoes oxidation in the various phytochemical reductions enumerated above, and in order to understand this it is necessary to consider the results obtained by Neuberg and his colleagues, which are discussed later on (p. 104).

"It has been shown by them that in all probability the production of alcohol and carbon dioxide from yeast proceeds by way of pyruvic acid, which is then decomposed by the carboxylase of the yeast (p. 73) into carbon dioxide and acetaldehyde, the latter being then reduced to alcohol. The formation of pyruvic acid from glucose involves a dehydrogenation and it is the hydrogen thus removed which serves for the reduction of the aldehyde. The reactions involved may be written as follows, the final products being italicised:

1. $C_6H_{12}O_6 = 2C_3H_6O_3$.
2. $2C_3H_6O_3 = 2C_2H_4O_3 + 4H$.
3. $2C_2H_4O_3 = 2CO_2 + 2C_2H_4O$.
4. $2C_2H_4O + 4H = 2C_2H_6O$.

"It has further been shown by Neuberg (p. 103) that it is possible, in several different ways, partially to protect the acetaldehyde from reduction and that the hydrogen thus rendered available is capable of effecting another reducing action, inasmuch as equivalent quantities of glycerol ($C_3H_8O_3$) are then produced, presumably by the reduction of an intermediate substance of the formula $C_3H_6O_3$ (see equation 1). The production of pyruvic acid, according to equation 2, is thus rendered possible and the fermentation continues. This suggests the possibility that the various substances capable of reduction by yeast might be supplied with the necessary hydrogen by deviation of some of the available hydrogen from the acetaldehyde, an equivalent amount of which would thus be protected from reduction and would be found among the products of fermentation," p. 82.

Wilder D. Bancroft

Physikalisch-chemische Mineralogie und Petrologie. *Die Fortschritte in den letzten zehn Jahren.* By Wilhelm Eitel. 22 X 15 cm; pp. vii + 174. Dresden and Leipzig: Theodor Steinkopff, 1925. Price: 8 marks paper, 9 20 marks bound. In the general part the author discusses the principles of equilibrium theory; inversions; caloric properties of the minerals; two-component, three-component, four-component, and multicomponent systems; the constituents of the magmas and of the earth's crust. In the much longer special part the author considers, among other things, silicate minerals, polynary minerals, magmatic gases, zeolites, weathering, the colloid chemistry of mineralogy, dolomite, salt deposits, metamorphic rocks, and crystalline shales.

On p. 5 it is pointed out that we get nearly the same curve for chrome steel, beta brass, and foams of soap, resins or gelatine, if we plot frequency against the number of sides of the polygons. On p. 9 there is a cut of Washburn's apparatus for measuring the viscosity of molten soda-lime glasses. On p. 11 is the statement that crystallized silver iodide is more strongly dissociated electrolytically than the fused salt. The information about beta alumina, p. 36, is not up to date. This modification is formed in presence of soda and goes back to the alpha form if heated long enough to drive off the soda.

Goldschmidt concludes, p. 39, that diamonds were formed at a depth of 60-100 kilometers. According to Chaudron and Forestier, p. 84, ferrous oxide is not stable above 570°, breaking up at that temperature into metallic iron and magnetite. Sosman and Hostetter consider, p. 36, that there is a strongly ferromagnetic modification of ferric oxide. The author does not consider the possibility, p. 110, of a calcium bicarbonate solution being wholly or in part a suspension of calcium carbonate peptized by carbon dioxide.

On p. 111 is the statement that Tammann and Pape have proved that kaolin breaks into alumina and silica when the water is driven off. This may be true; but it was so stated much earlier by Mellor. There is an interesting paragraph, p. 123, on the surface tensions of crystals and on the effect of change of surface tension on the rate of growth of different fads.

Wilder D. Bancroft

Die Allgemeinheit des Kolloidzustandes. By P. P. von Weimarn. Vol. I. *Second revised and enlarged edition.* 25 × 17 cm; pp. xvi + 504. Dresden and Leipzig: Theodor Steinkopff, 1925. This is not a book on general chemistry. It is a detailed account, from an avowedly inductive viewpoint, of the author's experiments to show that any substance can be obtained in a colloidal form. The author deserves all credit for having formulated this generalization nearly twenty years ago; but nobody questions this now and nearly five hundred pages as a starter seems excessive. The author's viewpoint has not changed much and he still considers liquids and gases as crystalline, though he now prefers to call them vectorial. As a historical record the volume is valuable but that is all that can be said for it. The method of presentation and the terminology are both bad.

Wilder D. Bancroft

Lehrbuch der Mikrochemie. By Friedrich Emich. *Second edition.* 25 × 16 cm; pp. 272. Munich: J. F. Bergmann, 1926. Price: 16.50 marks; 18.60 marks bound. The demand for a second edition of Prof. Emich's standard work on micro-chemistry, and the fact that this has had to be completely rewritten affords a proof—if proof were needed—of the correctness of the Author's statement in the Preface that few branches of scientific experimental work have experienced such a rapid development as that which includes micro-chemical practice. There can, in fact, be no doubt that micro-chemistry is daily becoming more generally recognised and more universally accepted as an ordinary branch of chemical procedure. It has a rapidly growing, and important literature, a technique, the ingenuity and beauty of which command our admiration, and last but not least a Journal—"Mikrochemie"—which is now in the fourth year of its existence, and volumes of which appear at fairly frequent intervals.

The work under review follows in its main outline the procedure generally adopted in other works dealing with this subject, one part being devoted to what may be described as general microchemistry, and a further part dealing with certain special reactions.

The general section is divided into three sub-sections dealing with (a) qualitative analysis, (b) quantitative analysis and (c) preparations. In the special part reactions are given for groups of cations and anions much as in the case of ordinary treatises on analytical chemistry, whilst in the organic part there is a division of the subject into methane derivatives, ordinary iso-cyclic derivatives, and finally, heterocyclic compounds.

The only way in which the accuracy of a book such as this can be properly assessed is by working with it as a bench companion for some considerable time, but in glancing through the book the Reviewer has derived the impression that the information is concise and accurate. At any rate that is the case with some sections with which he is specially acquainted.

The printing is good, and the illustrations are well chosen and clearly executed. This new edition of Prof. Emich's book is one which may be very warmly and confidently commended to chemists who are compelled from time to time—whether they like it or not—to work with very small quantities of materials, and there are, in ordinary practice, as the writer of this review has found on more than one occasion, problems, the solution of which can only be accomplished by the application of micro-chemical methods. As many of the processes described deal with the determination of physical constants the book cannot fail also to appeal to physicists.

It is perhaps to be regretted that the Author still regards the completeness of Prof. Pregl's handbook on elementary quantitative organic analysis a sufficient reason for dismissing that important subject in a page-and-a-half. There is, moreover, a tendency here and there to recommend a more or less complicated micro-chemical method where a simpler one is available, but these are slight defects in a work which, speaking generally, may be regarded as an admirable exposition of the subject.

A. Chaston Chapman

SOLUTIONS FOR COLORIMETRIC STANDARDS. I. SPECTRAL TRANSMISSION CURVES FOR SOME AQUEOUS SOLUTIONS CONTAINING ORGANIC INDICATORS OR INORGANIC SALTS

BY M. G. MELLON AND F. D. MARTIN

In undertaking a general study of the standards employed in various colorimetric analytical procedures, attention has been directed first to the set of indicators proposed by Clark and Lubs¹ for the determination of the concentration of hydrogen ions, and to the inorganic solutions suggested by Army and his students² for general colorimetric work. The object of the present paper is to report the results of certain spectrophotometric measurements made on systems containing these materials.

Color and Its Determination

The precise specification of characteristics which serve to distinguish an object exhibiting color is a matter involving considerable confusion and lack of uniformity in present practice. To state, for example, that the object is blue means little, for one might have in mind, in hue alone, anything ranging from that of Prussian blue to that of crystallized cupric sulfate. This unsatisfactory state of affairs existing in connection with the use and significance of colors is well recognized by the physicists. A general survey of the problem has recently been made by their colorimetry committee, the results of which have been published in a distinctly worthwhile report.³

As an introduction to the work being undertaken in this laboratory on solutions as standards of color, mention may properly be made of certain definitions and conclusions formulated by the committee on colorimetry, to which reference has just been made, and by a similar committee on spectrophotometry⁴. The quotations below have been taken from the reports of these two committees.

The entity color may be defined as "the general name for all sensations arising from the activity of the retina of the eye and its attached nervous mechanism, this activity being, in nearly every case in the normal individual, a specific response to radiant energy of certain wave-lengths and intensities." For solutions it is the result of the modification of the incident light by selective absorption of certain frequencies in the visible region of the spectrum. Any color can be completely specified psychologically by three fundamental characteristics, for which the following nomenclature has been suggested:

"Brilliance is that attribute of any color in respect of which it may be classed as equivalent to some member of a series of grays ranging from black

¹ J. Bact. 2, 1, 109, 191 (1917).

² Rept. 8th. Int. Congr. Appl. Chem. 26, 319 (1912); J. Am. Pharm. Assoc. 2, 76 (1913); Drug. Circ. 58, 131 (1914); J. Franklin Inst. 180, 199 (1915).

³ Troland et al: J. Optical Soc. America,—Rev. Sci. Instruments, 6, 527 (1922).

⁴ Gibson et al: J. Optical Soc. America,—Rev. Sci. Instruments, 10, 169 (1925).

to white." It is expressed as percent relative brightness, and indicates the portion of the total amount of white light (light with a spectral distribution of sunlight) falling upon a body which is reflected or transmitted. Absolute black has a brightness of zero and pure white 100 percent; that for any other color falls between.

"Hue is that attribute of certain colors in respect of which they differ characteristically from the gray of the same brilliance and which permits them to be classed as reddish, yellowish, greenish, or bluish. Dominant wave-length serves to express hue.

"Saturation is that attribute of all colors possessing hue which determines their degree of difference from a gray of the same brilliance." That is, it determines the degree in which the color possesses hue. It is expressed as percent purity, and denotes how red (or yellow, etc.) the color is.

As an example of the usage of these terms one might describe a color as having a brightness of 50 percent, a dominant wave-length of $690m\mu$, and a purity of 85 percent. In this case the brightness is moderately great, the dominant wave-length lies in the red portion of the visible spectrum, and the degree of saturation is relatively large. One would picture a fairly bright red. A red and pink having the same dominant wave-length will differ in the percent purity, the pink being the lower of the two, since it is an unsaturated red; that is, one having white admixed with it. The greater portion of white will give the pink a higher percent brightness than the red.

"The color of an object, considered as an impression which the object produces on the observer, is determined by at least three sets of factors: (1) the physical characteristics of the object, (2) the physical characteristics of the radiant energy falling upon or emitted by it, (3) and the nature and condition of the observer's visual apparatus. Our control over color in its technical applications is confined almost exclusively to the first two sets of factors, although the ultimate goal is always to be found in the consciousness of some observer. Practical colorimetry is therefore concerned with means for the unambiguous designation of those properties of objects and radiation which determine color perception."

The satisfactory determination of the colorimetric characteristics for a given system involves the determination of definite physical properties of the system, and the statement of the results obtained in terms which are likewise definite. "Most of the means actually employed, however, utilize the visual apparatus of an observer as an essential element, and hence are frequently not independent of the nature and special condition of this apparatus."

For the specification and testing of color in technical work there have come into more or less extensive use several systems which are arrangements based upon color matching with arbitrary standards, such as colored glasses for tintometers or variegated pigments for the systems of Munsell, Ridgway, or Ostwald. To specify a color by reference to stimuli by these methods involves the specification of a stimulus empirically found to evoke the same color.

But when one desires, on the side of the stimulus, the fundamental method of colorimetric specification a spectrophotometric method is employed. By

means of the spectrophotometer one can specify the identical radiant energy actually evoking the color, and at the same time take advantage of a procedure which is actually independent of the observer. "The characteristics of physical objects which determine their colors, when viewed by radiation from other sources, can be expressed almost completely by means of spectral reflection or transmission curves, representing as a function of the wavelength or frequency, the fraction of the original radiation impinging upon the object, which finally leaves it as reflected or transmitted rays, respectively. Such curves are most readily determined by means of a spectrophotometer. For the intercomparison of the color values of objects, without reference to the radiation by which they are viewed or the observer's visual system, reflection or transmission curves are of great value in colorimetrics, although such curves represent properties of objects rather than of immediate stimuli to color."

A spectrophotometer was selected, therefore, as the proper instrument to use in determining the desired measurement of the colorimetric characteristics of the solutions under consideration.

Spectrophotometric Data

Spectrophotometric measurements on solutions, as carried out in this work, involve the determination of the transmittancies of the solutions; that is, the ratio of the transmission of a given cell containing the solution to the transmission of a duplicate cell containing pure solvent. Two colors may then be compared by simply comparing their transmittancy curves, the curve for any color conveying to the mind of an experienced observer something of the characteristics of the color itself.

In the direct use of such curves certain facts should be kept in mind¹. "Two colors which appear to match under one illumination may not appear to match under another. It is possible for two colors which appear matched in daylight to have the same brightness, dominant wave-length and purity, and yet each yield an entirely different spectral distribution curve when measured on a spectrophotometer. If, however, the two colors yield the same curve, they will not only have the same brightness, dominant wave-length and purity, but will appear matched under any illumination whatever." Priest² has shown that "if any two lights, however, different in spectral distribution, excite colors of the same quality, the wave-lengths of the center of gravity of their spectral distributions are coincident." But "two spectral distributions of light may have the same wave-lengths of center of gravity and not excite colors of the same quality if the lights in the two cases are distributed over different ranges of wave-length."

Although spectrophotometric data constitute a fundamental specification of a color stimulus, as such, and may be of wide use without conversion to other terms, it should be noted that one may desire to specify the color

¹ Keuffel and Esser: Technical Bulletin with Color Analyzer.

² J. Optical Soc. America—Rev. Sci. Instruments, 4, 388 (1920).

stimulus in terms of the sensation it produces rather than to use the curve itself. Such curves suffer as a means of colorimetric specification in that they cannot readily be interpreted as color.

In some cases it is advantageous to use the trichromatic system which involves a calculation of the elementary color excitation values; that is, the percentage red, green and violet excitations produced by the color of the given sample. To become determinative of a definite color in this manner spectral distribution curves "require combination with a certain energy distribution, representative of the particular source by which the object is viewed." A given solution might then be designated as producing a sensation of 5 percent violet, 20 percent green, and 75 percent red.

In other cases the specification of the three attributes of color—brilliance, hue, and saturation—for any given color completely describes the color as it appears in sunlight to the normal eye. As already indicated, a color may then be described as having, for example, a brightness of 40 percent, a dominant wave-length of $500m\mu$, and a purity of 70 percent. The determination of these characteristics is known as monochromatic analysis.

Apparatus and Materials

The spectrophotometer used was a Keuffel and Esser color analyzer with a constant deviation spectrometer and disk photometer which gave direct readings for wave-length and percentage transmission. This instrument has been sufficiently described by Brode¹, by Keuffel², and by Ferry³.

In using the analyzer settings of the sector for 0, 25, and 100 percent were checked at the beginning of each day's run, while the wave-length scale was checked with the yellow D line of the sodium flame for every second sample. Although a precision of one percent is claimed for the instrument, it is doubtful whether this limit was reached. The eye rather quickly lost its sensitivity to small differences in intensity during a long series of readings, especially in the violet region, where the sensitivity is not very great under normal conditions. Frequent shifts from one eye to the other help to reduce this fatigue. Also some lost motion was encountered in adjusting the photometer disks. The errors resulting were partly compensated by taking the average of several readings. Part of the data were obtained by setting the instrument for a given transmittancy and reading the wave-length for that transmittancy, and part by the reverse process.

The solutions were contained in glass-lined cells 5 cm in length. One contained the solvent alone, and the other the solvent plus the compound being measured. 100 watt, nitrogen-filled, tungsten bulbs (with 110 volt, A. C. current) were used in the analyzer. While the temperature of the room varied from 22° to 26°C. during the entire work, the change during the determination on any one solution was not over one degree.

³ "Physics Measurements," I, 239 (1926).

Commercial indicators were used, the solutions indicated in Table I being prepared as follows: thymol blue, brom-phenol blue, brom-cresol purple, brom-thymol blue, phenol red, and cresol red by the method of Clark¹, using aqueous solutions of the alkali salts; the newer indicators of Cohen²—chlor-phenol red, brom-phenol red, brom-chlor-phenol blue, and brom-cresol green—by the same procedure; methyl red was dissolved in 50 percent ethyl alcohol, while the 95 percent solution was used for ortho-cresolphthalein, phenolphthalein, and the nitro-phenols (the latter were adjusted with sodium hydroxide or hydrochloric acid until practically colorless); and methyl orange was prepared in aqueous solution.

TABLE I
Indicators used

Name	Concentration	pH Range	pH of Buffers
1.—Methyl orange	0.05%	3.0- 4.6	2.4- 5.0
2.—Thymol blue	0.04	1.2- 2.8	1.0- 3.2
3.—Brom-phenol blue	0.04	3.0- 4.6	2.4- 5.0
4.—Methyl red	0.05	4.4- 6.0	4.0- 6.4
5.—Brom-cresol purple	0.04	5.2- 6.8	4.8- 7.2
6.—Brom-thymol blue	0.04	6.0- 7.6	5.6- 8.0
7.—Phenol red	0.02	6.8- 8.4	6.4- 8.8
8.—Cresol red	0.02	7.2- 8.8	6.8- 9.2
9.—Thymol blue	0.04	8.0- 9.6	7.6-10.0
10.—2, 4 dinitrophenol	0.04	2.0- 4.7	— 4.8
11.—p-nitrophenol	0.04	5.0- 7.0	— 7.4
12.—m-nitrophenol	0.04	6.3- 9.0	— 9.4
13.—Phenolphthalein	0.04	8.3-10.0	—10.2
14.—Cresolphthalein	0.04	8.2- 9.8	—10.2
15.—Chlor-phenol red	0.04	5.0- 6.6	4.6- 7.0
16.—Brom-phenol red	0.04	5.4- 7.0	5.0- 7.4
17.—Brom-chlor-phenol blue	0.04	3.2- 4.8	2.8- 5.2
18.—Brom-cresol green	0.04	4.0- 5.6	3.6- 6.0

The buffer solutions for the indicators were selected with pH values sufficiently above or below the normal range of the indicator to insure practically complete transformation to either the basic or acidic form. These solutions were prepared according to the directions of Clark³, using salts which had been recrystallized three times from conductivity water.

In preparing the inorganic solutions cupric sulfate, cobaltous chloride, ammonium dichromate, and potassium dichromate were recrystallized from conductivity water. Ferric chloride was obtained by passing chlorine over ferric oxide heated in a combustion furnace and the product sublimed. Chloropentammino-cobaltic chloride was prepared by the method of Willard⁴. In

¹ "Determination of Hydrogen Ions," p. 80 (1923).

² U. S. Public Health Reports, **38**, 199 (1923).

³ "Determination of Hydrogen Ions," p. 106 (1923).

⁴ J. Am. Chem. Soc., **44**, 2220 (1920).

standardizing the solutions the copper and cobalt were determined electrolytically, and iron and chromium gravimetrically. The potassium dichromate was weighed directly. Solutions of cupric sulfate, ferric chloride, and cobaltous chloride were made to contain one percent hydrochloric acid, as recommended by Arny¹. The ammoniacal solutions of cupric sulfate, ammonium chromate, and chloro-pentammino-cobaltic chloride contained 2.8 percent ammonia. In diluting any of these solutions, the concentration of acid or base was kept constant. An aqueous solution of potassium dichromate was used. All these solutions were preserved in Pyrex glass in the dark and showed no visible evidence of decomposition after standing a year, except for traces of a precipitate in the solution of ammoniacal cupric sulfate.

In his directions for the preparation of the standards for the determination of the concentration of hydrogen ions Clark² recommends the addition of specified amounts of the solution of the indicator, prepared on a percentage basis, to a definite amount of the buffer solution—usually 5 drops of the indicator, of the concentration shown in Table I, to 10 ml of the buffer. Since one of the objects in mind was to determine the colorimetric characteristics of these standards, it seemed advisable in this case to follow the recommended procedure for preparing solutions rather than to use the molar system for expressing concentrations. Assuming that 1 ml is equivalent to 25 drops, the solution prepared by adding 1 ml of the solution of the indicator to 50 ml of the buffer solution represented a concentration approximately equal to that mentioned above. One or more solutions of other concentrations were measured for each compound.

Experimental Data

Figs. 1-10 show the data obtained. The curves are plotted with wavelengths as abscissa on an ordinary scale and percent transmittancy as ordinates on a logarithmic scale. Appel and Brode³ noted that this type of curve gives a good representation of the absorption as it appears to the eye. These investigators used the negative logarithm of the transmittancy as the ordinates. This quantity is, on the basis of Beer's Law, directly proportional to the product of the concentration and thickness.

Discussion and Summary

A discussion of the general significance of the data presented, in relation to the use of solutions for colorimetric standards, is reserved for a later communication.

As already indicated; spectral transmission curves serve as fundamental data for various uses. With the curve determined, one may calculate values for the color sensation that will be experienced for illumination by a given source, providing the spectral distribution of the source is known. General

FIG. 1

Spectral transmission curves for the following systems: aqueous solution (containing 1% hydrochloric acid) of cupric sulfate, ferric chloride, and cobaltous chloride. For each of these salts curves 1, 2, 3 and 4 are for M/4, M/8, M/16, and M/32 solutions, respectively.

FIG. 2

Spectral transmission curves for the following systems: aqueous solution of potassium dichromate—curves 1, 2 and 3 are for M/6, M/60 and M/300 solutions, respectively; aqueous solution (containing 2.8 percent of ammonia) of ammonium chromate—curves 1, 2 and 3 are for M/300, M/600 and M/1200 solutions, respectively; and aqueous solutions (containing 2.8 percent ammonia) of tetrammino-cupric sulfate and chloropentamminocobaltic chloride—for each of these salts curves 1, 2 and 3 are for M/100, M/200 and M/400 solutions, respectively.

FIG. 3

Spectral transmission curves for the following systems: cresolphthalein at pH 10.2—curves 1, 2 and 3 are for 1.0, 0.5 and 0.25 ml, respectively, of the indicator solution in 50 ml of buffer solution; and m-nitro-phenol at pH 9.4 and dinitro-phenol at pH 4.8—curves 1 and 2, for each of these indicators, are for 4 and 2 ml, respectively, of the indicator solution in 50 ml of buffer solution.

FIG. 4

Spectral transmission curves for the following systems: methyl red at pH 6.4 (circles with line)—curves 1, 2 and 3 are for 4.0, 2.0 and 1.0 ml, respectively, of the solution of the indicator in 50 ml of the buffer solution; methyl red at pH 4.0 (circles)—curves 1, 2 and 3 are for 5.0 and 2.5 and 1.25 ml, respectively, of the solution of the indicator in 50 ml of the buffer solution; brom-phenol blue at pH 5.0 (dots with line) and at pH 2.4 (dots)—curves 1, 2 and 3 in each case are for 2.0, 1.0 and 0.5 ml, respectively, of the solution of the indicator in 50 ml of the buffer solution, while curve 4 is for 0.25 ml of the solution of the indicator.

FIG. 5

Spectral transmission curves for the following systems: methyl orange at pH 5.0 (circles with line—curves 1, 2, 3 and 4 are for 5.0, 2.5, 1.25 and 0.625 ml, respectively, of the solution of the indicator in 50 ml of the buffer solution; methyl orange at pH 2.4 (circles)—curves 1, 2 and 3 are for 5.0, 2.5 and 1.25 ml, respectively, of the solution of the indicator in 50 ml of the buffer solution; brom-thymol blue at pH 8.0 (dots with lines)—curves 1, 2 and 3 are for 2.0, 1.0 and 0.5 ml, respectively, of the solution of the indicator in 50 ml of the buffer solution; and brom-thymol blue at pH 5.6 (triangles)—curves 1, 2 and 3 are for 4.0, 2.0 and 1.0 ml, respectively, of the solution of the indicator in 50 ml of the buffer solution.

FIG. 6

Spectral transmission curves for the following systems: p-nitrophenol at pH 7.4—curves 1 and 2 are for 2 and 1 ml, respectively, of the indicator solution in 50 ml of buffer solution; phenolphthalein at pH 10.2—curves 1, 2 and 3 are for 2.0, 1.0 and 0.5 ml, respectively, of the indicator solution in 50 ml of buffer solution; and brom-chlor-phenol blue at pH 2.8 (circles) and at pH 5.2 (circles with line)—curves 1 and 2 for each pH value are for 2 and 1 ml, respectively, of the indicator solution in 50 ml of the buffer solution, while curve 3 is for 0.5 ml in the same volume of buffer solution.

FIG. 7

Spectral transmission curves for the following systems: brom-cresol purple at pH 4.8 (circles) and chlorphenol red at pH 4.6 (dots)—curves 1, 2 and 3 are for 4.0, 2.0 and 1.0 ml, respectively, of the solution of the indicator in 50 ml of the buffer solution; and brom-cresol purple at pH 7.2 (circles with line) and chlor-phenol red at pH 7.0 (dots with line)—curves 1, 2 and 3 are for 2.0, 1.0 and 0.5 ml, respectively, of the solution of the indicator in 50 ml of the buffer solution.

FIG. 8

Spectral transmission curves for the following systems: brom-cresol green—at pH 6.0 (circles with line)—curves 1, 2 and 3 are for 2.0, 1.0 and 0.5 ml, respectively, of the solution of the indicator in 50 ml of the buffer solution; brom-cresol green at pH 3.6 (circles)—curves 1, 2 and 3 are for 4.0, 2.0 and 1.0 ml, respectively, of the solution of the indicator in 50 ml of the buffer solution; phenol red at pH 8.8 (dots with line — curves 1 and 2 are for 1.0 and 0.5 ml, respectively, of the solution of the indicator in 50 ml of the buffer solution; and phenol red at pH 6.4 (dots)—curves 1, 2 and 3 are for 2.0, 1.0 and 0.5 ml, respectively, of the solution of the indicator in 50 ml of the buffer solution.

FIG. 9

Spectral transmission curves for thymol blue for the following pH values: 1.0 (circles), 3.2 (circles with line), 7.6 (crosses), and 10.0 (dots). For pH values 1.0, 3.2 and 10.0 curves 1, 2 and 3 are for 2.0, 1.0 and 0.5 ml, respectively, of the solution of the indicator in 50 ml of the buffer solution. For pH value 7.6 curves 1, 2 and 3 are for 4.0, 2.0 and 1.0 ml, respectively, of the solution of the indicator in 50 ml of the buffer solution.

FIG. 10

Spectral transmission curves for the following systems: brom-phenol red at pH 7.4 (dots with line)—curves 1 and 2 are for 2.0 and 1.0 ml, respectively, of the solution of the indicator in 50 ml of the buffer solution; brom-phenol red at pH 5.0 (dots) and cresol red at pH 9.2 (circles with line)—curves 1, 2 and 3 in each case are for 2.0, 1.0 and 0.5 ml, respectively, of the solution of the indicator in 50 ml of the buffer solution; and cresol red at pH 6.8 (circles)—curves 1, 2 and 3 are for 4.0, 2.0 and 1.0 ml, respectively, of the solution of the indicator in 50 ml of the buffer solution.

information relating to this calculation and to the specification of color in terms of relative brightness, dominant wave-length and purity are included in the references mentioned.¹

It should be noted that Brode², in proposing a spectrophotometric method for the determination of the concentration of hydrogen ions in solutions of dyes, presented curves for several indicators, using a single concentration of the indicator in solutions of different pH values. The present measurements on the transmittancy in the visible range for a number of systems furnishes a check on the minimum point of his curves; that is, the wave-length of maximum absorption. Also it includes, in addition to data for Arny's solutions of inorganic salts, data for the same indicators at other concentrations, and for a number of other indicators, including four of those recently proposed by Cohen.

THE CATALYTIC MINIMUM POINT. II. THE IODINE-ACETONE REACTION IN BUFFER SOLUTION*

BY MILTON BERGSTEIN**

The iodine-acetone reaction has been investigated to some extent in the past because of its apparent simplicity. Dawson and Powis¹ after extensive studies of the reaction in acid solution came to the conclusion that the velocity of the reaction is directly proportional to the concentrations of acetone and acid and independent of the concentration of iodine. Rice and his co-workers² also studied the ketone-halogen reactions catalyzed by acids and in passing arrived at the same conclusion.

The former investigators found in studying the autocatalyzed reaction

in distilled water that the initial velocity (determined by extrapolation to zero time) is considerably greater than that readily accounted for on the assumption that hydrogen ion alone is active in pure water (water of approximately pH 7) and concluded after several experiments that the initial speed in neutral solution is due to some substance or substances, the activity of which is greatly depressed by the addition of an acid and suggested one of basic nature. This autocatalyzed reaction has been studied further as previously reported.³ The phenomena observed were used to determine the point of minimum velocity (the catalytic minimum point) of this reaction and to test the effect of variation of temperature and of concentration of neutral salt on the minimum point.

Rice and his coworkers found in the course of their work, in attempting to stop the reaction by running the mixture into approximately neutral buffer, that the reaction was not stopped, that it continued at considerable speed, and that at this pH of approximately 7 it went to completion within a day. Accordingly it was considered advisable to make some study of a ketone-halogen reaction in alkaline solution and particularly near the neutral point of pure water. This paper is the report of such an investigation. There is further reported a direct determination of the catalytic minimum point in buffer solution. The iodine-acetone reaction was selected for particular study.

Catalysis near the Neutral Point of Pure Water

All the experiments reported in this part were conducted at $25^{\circ} \pm .02$ in the standard sodium-potassium phosphate buffer mixtures of Sørensen recommended by Clark.¹ A series of determinations (not recorded herein) at arbitrary phosphate concentrations showed that the rate of the reaction

is directly proportional to the concentration of acetone and apparently does not depend on the concentration of iodine. The H^+ ion liberated is without effect on the rate of the reaction since it is immediately neutralized by the buffer. This point is discussed later.

In some experiments (also not recorded here) it was attempted to study the rate of this reaction in a buffer from the initial point to the end of the reaction. This was found impracticable. Solutions were made up in volumetric flasks by adding the required weights of buffer salts to solutions of potassium iodide and iodine in the quantities desired, and filling not quite to the mark with distilled water. In the procedure finally adopted a known weight of acetone was added from a calibrated pipette, the flask was filled to the mark with distilled water and thoroughly shaken, and, by means of a quick-running syphon, the solution was then transferred to glass-stoppered reaction vessels which held about 80 cc each. The reaction vessels were immediately placed in the thermostat. Zero time was noted (for the sake of reference and not because it was needed in the calculations) as the time when the acetone started to run into the solution. The time elapsed from zero time to that when the flasks were placed in the thermostat was usually less than four minutes and never over five. A method can be devised whereby the initial iodine concentration may be known in order to study the reaction in its entire range. However, acetone has a positive heat of solution in water, and the dissolving of 10 to 20 cc in a liter of solution has a temperature effect which influences the velocity of the reaction appreciably. It was for this reason, also, that the solutions were brought only approximately to the temperature of the thermostat before starting the reactions. The first samples were removed from the reaction vessels with calibrated pipettes at least fifteen minutes after they were introduced into the thermostat. It was found by making heating and cooling curves that the contents of flasks such as used always reached the temperature of the thermostat within that time. The samples were run into known quantities of standard sodium thiosulfate solution and titrated using starch to the disappearance of blue with thiosulfate solution from a weight burette. It was found, as reported by Rice and Fryling, that the employment of a blue light-source facilitated observation of the end-point. The time noted as final in each case was that when the sample started to run into the thiosulfate solution.

To determine the velocity constants for an experiment the titre in grams of sodium thiosulfate solution was plotted against the time and drop in titre per minute calculated directly from the graph. It should be noted that the concentration of acetone in all these runs was practically constant since it was

¹ Clark: "The Determination of Hydrogen Ions," 2nd Ed., p. 114 (1923).

so much in excess of the concentration of iodine. Fig. 1 (Experiment 164 c) is an example of the type of curve obtained. It may be noticed that there are

two very flat portions. In the experiments excluding 164b and 164c these flat portions appeared to be two intersecting straight lines. The velocity constants k_1 and k_2 are for the first and second "straight" lines respectively. They are calculated from the formula

$$k = \frac{\text{drop/min.} \times \text{molarity Na}_2\text{S}_2\text{O}_3}{\text{cc of sample} \times \text{molar conc. of } (\text{CH}_3)_2\text{CO}}$$

Table I gives the results of a typical experiment. Time is expressed in minutes. Titre is expressed in grams of sodium thiosulfate solution per volume of sample taken.

In the graphs of the individual experiments the "straight" lines already referred to are definite and clear. However, it is obvious on reference to Table II that, in spite of the apparent regularity of the experiments as judged from the graphs, too much significance should not be attached to the values for k_1 calculated from the first "straight" line. My experience indicates that although it is relatively simple to obtain check results for k_2 the same is not true for k_1 . It is this observation in particular which forces the conclusion that the "straight" line in the initial part of the reaction is probably illusory.

FIG. 2

It is further evident from Table II that there is a regular variation of k_2 with concentration of potassium iodide. As the concentration of potassium iodide increases, values of k_2 , the velocity constant for the second part of the reaction, decrease. This result is in qualitative agreement with the observations of Brönsted and King¹ and of Kilpatrick² on the "secondary kinetic salt effect" in a hydroxyl ion catalyzed reaction in phosphate buffer.³ The variation of k_2 with concentration of potassium iodide is plotted in Fig. 2. The results obtained indicate definitely that I^- ion is not catalytically active in this reaction.

In Table II the values listed under I_1 indicate the approximate decrease in molarity of iodine in the reaction mixture when the first cloudiness was observed in the solutions. This cloudiness is due to the precipitation of iodoform. The time when this cloudiness was first noted was recorded for each experiment. From this data it was possible to calculate approximately the amount of iodine which disappeared before any iodoform precipitated. Those places marked "n" indicate that in those reactions no precipitation of iodoform was observed. It is noteworthy that increase in concentration delays the precipitation of iodoform although it affects the shape of the reaction curve

¹ Brönsted and King: J. Am. Chem. Soc., **47**, 2523 (1925).

² Kilpatrick: J. Am. Chem. Soc., **48**, 2091 (1926).

³ Brönsted and Teeter: J. Phys. Chem., **28**, 579 (1924); Brönsted and King: loc. cit.

not at all. The location of the point where the first "straight" line cuts the second "straight" line (called here the "break-point") is likewise but slightly affected by variation in concentration of potassium iodide. Precipitation of iodoform occurred always after the "break-point." This point will be referred to later.

FIG. 3

Table III reviews the variation of the velocity constant, k_2 , with hydrogen ion concentration and with hydroxyl ion concentration (which is equal to $10^{-14}/[\text{H}^+]$). The results are plotted in Fig. 3. Values for I_2 are also given.

Theoretical. The mathematical unravelment of the reactions involved is an impossibility with the data at hand. There are probably reactions involving simultaneous and successive formation of mono-iodoacetone, di-iodoacetone, tri-iodoacetone, and iodoform. The concentrations of these substances together with those of acetone, iodine, hydroxyl ion (presumably a constant in buffer solution), hydrogen ion, iodide ion, and triiodide ion may be designated as variable factors. The effect of hydrogen ion is negligible at the concentrations at which it exists in alkaline solution. The results given in Table II likewise indicate that, for the low concentrations of iodine and potassium iodide in the reaction mixtures, iodide and triiodide ions also have a negligible effect. The point has previously been made that the liberation of hydrogen ion during the course of the experiment has no effect on the concentration of hydroxyl ion since any hydrogen ion formed is taken up by the buffer. This, of course, is not wholly true. It is possible that during the second part of the reaction there is a tendency toward constant "speeding up" due to the liberation of some autocatalyst but that this effect is neutralized because of the slow simultaneous removal of hydroxyl ion which is also a catalyst for the reaction. It should be noted here that in all the experiments reported the total molarity of hydrogen ion liberated at the end of the reaction was less than one twelfth of the molarity of the buffer salts—a ratio small but not negligible. The variation in concentration of acetone is insignificant.

TABLE III

Effect of Variation of Hydrogen and Hydroxyl Ion Concentrations on Reaction Velocity Constant, k_2 , in Phosphate Buffer.

Exp.	pH	$[\text{H}^+] \times 10^7$	$[\text{OH}^-] \times 10^7$	$k_2 \times 10^4$	I_2
159	6.468	3.40	0.294	0.470	0.0017
156	6.643	2.28	.439	.647	—
154d	6.813	1.56	.641	.924	.0015
155	6.979	1.02	.980	1.129	.0012
160	7.168	.679	1.473	1.521	.0012

It can be shown that because there are apparently a few successive reactions it is necessary to know the initial velocity of disappearance of iodine in order to obtain any information as to the values of the several velocity constants of the reactions involved. It has been previously pointed out, however, that it was impossible to measure the rate of the reaction in the initial part since the solution of the small quantity of acetone used raised the temperature of the mixture; it was necessary to wait at least fifteen minutes for the reaction mixture to reach the temperature of the thermostat before the rate of reaction could be studied.

The objection may be made that the peculiar nature of the results obtained may be attributed to the method of titration employed. Speed of titration is an important factor. An indication of the speed with which these titrations were made may be drawn from the fact that it was common practice to remove a sample from the thermostat, titrate it with thiosulfate, weigh the burette, and remove another sample from the thermostat ready for titration all within four minutes. With such speeds little trouble is encountered due to "fading" of the end-point. The serious objection may be made that at the pH values employed there was no justification for the use of sodium thiosulfate since in alkaline solution sulfate as well as tetrathionate is formed by the reaction of thiosulfate with iodine. Kolthoff¹ found that a solution of pH less than 6.5 must be used in titrating 0.01 N iodine and that for 0.001 N iodine the pH should be less than 5. However, the error is of a nature which will affect not the shapes of the curves but only the slopes of the "straight" lines.

The possibility that iodoform may be a catalyst for the reaction is suggested by the fact that the "break-point" already referred to occurs just before the precipitation of iodoform; the idea is suggested that when the iodoform attains the constant concentration corresponding to its solubility the reaction attains maximum and constant speed. In direct test of this theory an attempt was made to study the effect of iodoform dissolved in the reaction mixture. Vulpius² reports that 0.106 g of iodoform dissolve in a liter of water. Judging from the difficulty of solution of the iodoform (0.1 g were never dissolved in a liter of water no matter what means was used) the author is of the opinion that the value reported for the solubility of iodoform in water is much too high. In testing the catalytic activity of iodoform, many precautions were taken to insure saturation of the solution; nevertheless, the initial speed was never increased nor was precipitation of iodoform observed in any of the experiments until the usual time after the "break-point" which was never appreciably shifted. In this connection it is well to remember that although the character "break-point" was observed in solutions containing high concentrations of potassium iodide no precipitation of iodoform was observed even on long standing or after prolonged shaking although its odor was pronounced.

Temperature Coefficient. Rice³ reported that I measured the value of k_{35}/k_{25} for the reaction between acetone and iodine when catalyzed by an

¹ Kolthoff: *Z. anal. Chem.*, **60**, 338 (1921).

² Vulpius: *Pharm. Centralbl.*, **34**, 117 (1893).

³ Rice: *J. Am. Chem. Soc.*, **45**, 2808 (1923).

alkaline buffer solution and found it to be 2.52. In the experiment referred to, I employed the "two-thermostat" method¹ and compared the velocities of the initial "straight" lines. In the light of later knowledge I came to the conclusion that the method was subject to two criticisms for this reaction: (1) I did not take into account the initial temperature effect due to the solution of acetone; (2) because of the anomalous results obtained with the initial straight lines they ought not to be compared directly.

In two experiments at pH 6.8₁₃ in phosphate buffer at 35° values of 3.34 and 3.38×10^{-4} were obtained for the velocity constant, k_2 . Comparison of these values with that of 0.924×10^{-4} for equivalent salt concentration at 25° (see Table II) gives a value for k_{35}/k_{25} of 3.61 at pH 6.8₁₃ in phosphate buffer. This is somewhat higher than for the hydrogen ion catalyzed reaction, a result contrary to that expected from the proton theory of catalysis.²

Catalysis near the Catalytic Minimum Point

The range of hydrogen ion concentrations from pH 3.04 to pH 6.3₁ is adequately covered by Walpole's sodium acetate-acetic acid and sodium acetate-hydrochloric acid standard buffer solutions.³ The iodine-acetone reaction was studied colorimetrically in such solutions in the following way. To a number of 100 cc volumetric flasks containing solutions of buffers which would give exactly known concentrations of hydrogen ion when the flasks were filled to the mark were added about 2 cc of starch solution each and exactly equal volumes of acetone measured out from a pipette. The flasks were filled almost to the mark and placed in the thermostat to attain temperature. After the lapse of about twenty minutes they were removed singly; equal volumes of iodine solution of fixed concentration were added from a pipette; the time was noted as initial when the iodine solution began to run in; and the flasks were quickly filled to the mark, shaken, and returned to the thermostat. The time when the iodine-starch blue color just disappeared was noted as final time for each bottle. The difference in times was the time recorded for the reaction. The catalytic minimum point reported is the pH determined graphically at which maximum time is required for the disappearance of the blue color. In order to obviate error sodium acetate solutions made up in several different ways were used. The same precautions were taken with the acetic acid and hydrochloric acid solutions. In some experiments in order to eliminate the possible effects of starch, solutions of the latter were added just before completion of the reaction. In all cases practically the same values were obtained for the catalytic minimum point. Further to ensure the accuracy of the method blanks were made up containing no acetone. The blue color remained unchanged in one such bottle after the lapse of a year whereas with acetone present it would disappear in about an hour.

Three experiments in acetic acid-sodium acetate buffer at 25° yielded pH values for the catalytic minimum point of 3.8, 3.8, and 3.87. At 40° pH values of

¹ Rice and Kilpatrick: loc. cit.

² Rice: loc. cit.

³ Walpole: J. Chem. Soc., 105, 2501 (1914).

3.82 and 3.84 were obtained. In hydrochloric acid-sodium acetate buffer at 25° the catalytic minimum point was found to be at pH 3.95. The mean of these values is pH 3.85, and it is obvious that neither for a temperature variation of 15° nor for a change in the buffer salt does the catalytic minimum point vary much from this value. This value is of an order ten times as great as that obtained by extrapolation in studying the autocatalyzed reaction.¹

Part of this shift may be explained on the following reasoning. The term dx/dt in the autocatalytic equation,² $dx/dt = (a - x) [k_H(c + x) - k_{OHd}]$, although measured by disappearance of I_2 does not represent the rate of this disappearance but the rate of the initial iodine-acetone reaction. The hydroxyl ion has only its normal or non-specific influence on this reaction but is apparently solely responsible for the succeeding reactions in which more iodine is removed practically instantaneously with the eventual formation of iodoform. The effect of these reactions is by liberation of more hydrogen ion to bring the reaction more rapidly to the catalytic minimum point. This point is unchanged for the primary reaction itself. At this point its velocity is a minimum and on the acid side of it its velocity again increases although the velocity of the second reactions (forming di-iodoacetone, etc.) rapidly falls off to an infinitesimal of another order. In the buffer solution method for determining the catalytic minimum point, the rate measured is that of disappearance of iodine. Because it catalyzes the secondary reactions, the hydroxyl ion is more active in effecting this disappearance of iodine than is hydrogen ion at the true catalytic minimum point. The apparent catalytic minimum point is consequently shifted toward the acid side. The shift observed is at least two and a half times as great as can be accounted for on this basis. It may help to recall, however, that in phosphate buffers an apparent autocatalytic action was observed. There are, therefore, other catalysts for the iodine-acetone reactions and it may be the presence or generation of one of these in buffers which may account for the entire shift. For the iodine-acetone reaction the method of extrapolation offers the more trustworthy means for determination of the true catalytic minimum point.

Summary

1. The reactions between iodine and acetone have been studied in the vicinity of pH 7 and of the catalytic minimum point in buffer solution.
2. The reactions are complicated and the nature of the catalysts has not been fully established.
3. There is an approximately linear relationship between the velocity of the reactions in their later stages and the hydroxyl ion concentration near pH 7.
4. The temperature coefficient k_{35}/k_{25} for the second stage of this reaction at pH 6.813 in phosphate buffer has been determined to be 3.61. This is not in conformance with the proton theory of catalysis.

Bergstein and Kilpatrick: loc. cit.

Bergstein and Kilpatrick: loc. cit.

5. The apparent catalytic minimum point of this reaction has been found to be at pH 3.85 in acetate buffers. This figure is unchanged by a temperature variation from 25° to 40°.

The author wishes to express his appreciation to Professor F. O. Rice of Johns Hopkins University who directed the experimental work reported.

STUDIES IN ADSORPTION. PART XVII

Influence of Concentration of a Sol on its Coagulation by Electrolytes

BY S. GHOSH AND N. R. DHAR

In several papers¹ published from this laboratory the influence of change of concentration of a sol on its coagulation by electrolytes has been studied. It has been shown that, in general, the dilution rule, viz. the greater the concentration of a sol the greater is the amount of an electrolyte necessary for coagulation, is valid for those sols, which are not capable of adsorbing appreciably the ions carrying the same charge as the sol from the coagulating electrolytes. On the other hand, those sols, which appreciably adsorb ions carrying the same charge as the sol, do not follow the general dilution rule when coagulated by monovalent precipitating ions. In previous papers the general dilution rule has been found to be applicable to the sols of ferric hydroxide (positive and negative), chromium hydroxide (positive and negative), and stannic hydroxide (negative), whilst the rule is not applicable to the sols of arsenious sulphide, antimony sulphide, mastic and prussian blue.

In the present paper we have extended our investigations on the influence of concentration of the sols of antimony sulphide, stannic hydroxide and (positive) manganese dioxide (positive and negative), aluminium hydroxide, thorium hydroxide, vanadium pentoxide, prussian blue, uranium ferrocyanide, gum dammar, gamboge, sulphur (Weimarn), gold and silver, towards their coagulation by various electrolytes.

We have also determined the adsorption of both positive and negative ions from an electrolyte by a positively charged sol of manganese dioxide as well as by freshly precipitated manganese dioxide, and we have shown that our results on adsorption support our views based on the phenomenon of adsorption to explain the abnormal behaviour of a sol on dilution.

Antimony Sulphide Sol

We have already shown that both arsenious sulphide and antimony sulphide sols behave abnormally towards dilution when coagulated by KCl, NaCl, KNO₃, etc., because these sols are capable of adsorbing appreciable quantities of similarly charged Cl⁻, NO₃⁻ ions, etc., from these electrolytes. We have however, shown with a sol of arsenious sulphide that this sol behaves normally towards dilution when coagulated by salts like AgNO₃, methyl violet, quinine hydrochloride, strychnine hydrochloride, etc. This is because as we have already indicated, the cations from AgNO₃, methyl violet, quinine hydrochloride, strychnine hydrochloride, etc., are highly adsorbed in comparison with anions. In Table I the results are given as obtained by us when antimony sulphide sol is coagulated by these electrolytes:—

¹ J. Phys. Chem., **26**, 701 (1922); **28**, 313 (1924); **29**, 435, 659 (1925); Kolloid-Z., **34**, 262 (1924); **36**, 129, (1925).

TABLE I

Coagulation of antimony sulphide sol by alkalids, dyes, etc.

Concentration of the sol = 0.54 grms. Sb_2S_3 per litre.

5 c.c. of the sol made up to 10 c.c. = Sol A.

Volume = 10 c.c.; time = $\frac{1}{2}$ hour.

Electrolyte	Amount to coagulate in c.c.		
	Sol A	Sol A/2	Sol A/4
AgNO_3 M/6.25	0.6	0.45	0.30
Quinine hydrochloride M/2160	0.40	0.20	0.15
Strychnine hydrochloride M/1210	1.45	0.95	0.70
Methylene blue M/1832	3.50	1.80	1.00
$[\text{Co}(\text{NH}_4)_4\text{CO}_2] \text{NO}_3$ M/1320	2.05	1.60	1.10

It will be seen from Table I that when antimony sulphide sol is coagulated by AgNO_3 , quinine hydrochloride, strychnine hydrochloride, and methylene blue, the general dilution rule, viz., the greater the concentration of a sol the greater is the amount of an electrolyte necessary to coagulate it, is strictly followed with these electrolytes. These results are exactly similar to those obtained by us on the coagulation of arsenious sulphide sol by these electrolytes. The normal behaviour of antimony sulphide sol towards dilution when coagulated by either AgNO_3 or dyes and alkaloids is certainly due to very high adsorption of the cations in comparison with that of anions from these electrolytes. Antimony sulphide sol also behaves normally towards dilution when coagulated by a univalent cobalt ammine $[\text{Co}(\text{NH}_4)_4\text{CO}_2]\text{NO}_3$, because the cation having a large molecular weight is highly adsorbed by the sol.

Stannic Hydroxide Sol (positive)

A positively charged stannic hydroxide sol has been prepared by adding a dilute solution of caustic soda to a solution of stannic chloride in presence of small quantities of ferric chloride, till a precipitate just begins to form. The sol thus prepared is dialysed for a week to free it from electrolytes and was stored in a Jena glass flask. The sol thus prepared and dialysed is highly sensitive towards electrolytes and the coagulation experiments with this sol has to be finished in two days, otherwise the sol coagulates on standing. Table II shows the results obtained in the coagulation of this sol at different concentrations by various electrolytes:—

TABLE II

Concentration of the sol = 3.52 grams SnO_2 per litre

Sol A = 4 c.c. of the original sol made up to 10 c.c.

Volume = 10 c.c.; Time = 1 hour.

Electrolyte		Amount to coagulate in c.c.		
		Sol A	Sol A/2	Sol A/4
KBr	N/500	4.0	2.15	1.00
KCl	N/500	4.5	1.90	1.00
K_2SO_4	N/4000	3.3	1.20	0.50

The foregoing results show that the sol is very unstable towards electrolytes and behaves quite normally towards dilution when coagulated by monovalent and bivalent anions.

Manganese Dioxide Sol (negative)

This sol is obtained by treating a dilute solution of potassium permanganate with a dilute solution of hydrogen peroxide according to the method of Bredig and Marck.¹ The sol thus obtained is negatively charged and contains free alkali, which is obtained as the result of the reaction. It has been observed that the sol of a deep brown colour is less stable than that which has a reddish tinge due to the adsorption of permanganate ion, which certainly stabilises the sol. The manganese dioxide sol of a reddish brown colour was prepared and dialysed for about a week when it was free from alkali.

The coagulation of the negatively charged manganese dioxide sol has been investigated by Bredig and Marck,¹ Ganguly and Dhar.² Ganguly and Dhar used a sol containing gelatine and, therefore, the sol was not pure. In this paper we have carefully studied the coagulation of this sol purified by dialysis at different dilutions.

In Table III the results are reproduced:

TABLE III

Concentration of the sol = 0.80 grm. MnO_2 per litre.
2 c.c. of the sol made up to 8 c.c.
Volume = 8 c.c.; Time = 1 hour.

Electrolyte	Concentration	Amount added in c.c.	Precipitating concentration
KCl	N/20	1.15	0.00719
KBr	N/20	1.15	0.00719
KI	N/20	1.20	0.00750
K_2SO_4	N/20	1.25	0.00781
KNO_3	N/20	1.00	0.00625
KOH	N/20	2.80	0.01750
NaCl	N/20	1.35	0.00844
HCl	N/20	0.55	0.00344
AgNO_3	N/100	0.72	0.00090
BaCl_2	N/500	0.80	0.00020
MgCl_2	N/500	1.25	0.00031
MgSO_4	N/500	1.25	0.00031
CuSO_4	N/500	1.05	0.00026
$\text{Al}(\text{NO}_3)_3$	N/1000	2.40	0.00030
$\text{Th}(\text{NO}_3)_4$	N/1000	1.30	0.00016

¹ "Van Bemmelen Gedenkboek," 342 (1910).

² J. Phys. Chem., 26, 701 (1922).

An examination of Table III gives the following order for the precipitation values, beginning with the highest one: $\text{KOH} > \text{NaCl} > \text{K}_2\text{SO}_4 > \text{KI} > \text{KCl}, \text{KBr} > \text{KNO}_3 > \text{HCl} > \text{AgNO}_3 > \text{MgCl}_2, \text{MgSO}_4 > \text{Al}(\text{NO}_3)_3 > \text{CuSO}_4 > \text{BaCl}_2 > \text{Th}(\text{NO}_3)_4$.

From the experimental results, it appears that the Schulze-Hardy law is applicable to this sol with the exception of Al^{+++} ion, which possesses a higher precipitation value than either of the bivalent ion Ba^{++} or Cu^{++} . Moreover, of all the monovalent cations, Ag^+ ion possesses the greatest coagulating power. It is well-known that Ag^+ ions are highly adsorbed by MnO_2 ¹.

Table IV will show the effect of anions on the coagulation of negatively charged manganese dioxide sol.

TABLE IV

Electrolyte	Concentration	Amount added in c.c.	Precipitating concentration
KCl	N/20	1.15	0.00719
KBr	N/20	1.15	0.00719
KI	N/20	1.20	0.00750
KNO_3	N/20	1.00	0.00625
K_2SO_4	N/20	1.25	0.00781
KOH	N/20	2.80	0.01750

The precipitation values of different salts with the same cation K^+ is in the following order, beginning with the highest one $\text{KOH} > \text{K}_2\text{SO}_4 > \text{KI} > \text{KCl}, \text{KBr} > \text{KNO}_3$. The sol is about two and a half times more stable towards KOH than towards KCl. This shows that OH^- ions are appreciably adsorbed by manganese dioxide, as has been experimentally shown by Chatterji and Dhar.

Table V shows the influence of change in the concentration of the sol towards its coagulation by various electrolytes:—

TABLE V

Concentration of the sol = 0.80 grm. MnO_2 per litre.

Sol A = 2 c.c. of the sol made up to 8 c.c.

Volume = 8 c.c.; Time = 1 hour.

Electrolyte		Amount to coagulate in c.c.		
		Sol 2 A	Sol A	Sol A/2
KCl	N/20	1.30	1.15	1.00
K_2SO_4	N/20	1.35	1.25	1.10
KOH	N/20	2.80	2.80	2.70
AgNO_3	N/100	1.35	0.72	0.55
BaCl_2	N/500	1.20	0.80	0.45
$\text{Al}(\text{NO}_3)_3$	N/1000	>4.00	2.40	1.30
$\text{Th}(\text{NO}_3)_4$	N/1000	2.75	1.30	0.65

¹ Compare Chatterji and Dhar: *Kolloid-Z.*, **33**, 18 (1923).

It is obvious from our experimental results that the sol behaves normally on dilution towards all electrolytes (that is the greater the concentration of the sol the greater is the amount of an electrolyte necessary to coagulate the sol) except with KOH, the amount of which is practically constant for all the dilutions of the sol. We have shown that abnormality of a sol towards its dilution is intimately connected with the adsorption of the ion carrying the same charge as the sol. The tendency of KOH to behave abnormally on diluting manganese dioxide sol is, therefore, a direct consequence of the adsorption by OH' ions by the negatively charged manganese dioxide sol.

Positively Charged Manganese Dioxide Sol

When negatively charged manganese dioxide sol is coagulated by polyvalent cations like Fe⁺⁺⁺, Al⁺⁺⁺, Th⁺⁺⁺⁺, etc., it is observed that very small amounts of these cations are necessary to coagulate a given amount of the sol. If, however, greater quantities of these coagulating ions are added all at once, we have observed that coagulation does not occur and charge reversal takes place, the sol now moving to the cathode in an electric field.

A positively charged manganese dioxide sol is prepared by adding N/10 FeCl₃ solution to a litre of the negatively charged sol. The sol is of deep brown colour with a reddish tinge and is fairly stable. In order to free the sol from an excess of FeCl₃, it was dialysed for a week, when the filtrate obtained by coagulating the sol did not show any test for Fe⁺⁺⁺ ion. The results on the coagulation of this sol by a few selected electrolytes throw considerable light on the phenomenon of coagulation and are given in Table VI.

TABLE VI
Concentration of the sol = 0.92 gm. MnO₂ per litre
2 c.c. sol made up to 8 c.c.
Volume = 8 c.c.; Time = 1 hour

Electrolyte	Concentration	Amount added in c.c.	Precipitation value
KCl	N/20	1.8	0.01125
CuCl ₂	N/1	0.65	0.08125
KBr	N/20	1.75	0.01094
KNO ₃	N/20	1.60	0.01000
AgNO ₃	N/2.725	1.20	0.05505
K ₂ SO ₄	N/1000	0.80	0.00010
MgSO ₄	N/1000	0.90	0.00011
CuSO ₄	N/500	0.95	0.00024
KMnO ₄	N/400	0.55	0.00017

The following order is obtained from Table VI, beginning with the electrolyte possessing the greatest precipitation value:—

CuCl₂ > AgNO₃ > KCl > KBr > KNO₃ > CuSO₄ > KMnO₄ > MgSO₄ > K₂SO₄.

The sol being positively charged, it is evident that anions are the chief coagulating ions. An examination of Table VI reveals the fact that far greater

quantities of copper chloride, silver nitrate, etc., are necessary for coagulation than those of KCl, KNO₃, etc. This peculiar behaviour is certainly to be ascribed to the greater adsorption of cations like Cu⁺⁺ or Ag⁺ than that of K⁺ by MnO₂, so that the sol is partially stabilised by the adsorption of Cu⁺⁺ or Ag⁺ ions and more of an anion is necessary to coagulate the sol. It has already been shown in publications from this laboratory that manganese dioxide highly adsorbs copper or silver ions.¹ It is also seen from the above order of precipitation values that MnO₄' ion from KMnO₄ is as good a coagulating ion as the bivalent ion SO₄''. We have already observed that permanganate ions are highly adsorbed by manganese dioxide and stabilise the negatively charged manganese dioxide sol; and consequently, a greater concentration of KMnO₄ is necessary to coagulate the negatively charged sol than that of KCl or NaCl.

Table VII the influence of change of concentration of manganese dioxide sol (positively charged) on its coagulation by various electrolytes has been studied.

TABLE VII

Concentration of the sol = 0.92 grm MnO₂ per litre.

Sol A = 2 c.c. sol made up to 8 c.c.

Volume = 8 c.c.; Time = 1 hour

Electrolyte		Amount to coagulate in c.c.		
		Sol 2 A	Sol A	Sol A/2
KCl	N/20	2.0	1.80	1.60
CuCl ₂	N	0.55	0.65	0.75
KBr	N/20	2.0	1.75	1.60
KNO ₃	N/20	1.6	1.4	1.0
AgNO ₃	N/2.725	1.1	1.2	1.3
K ₂ SO ₄	N/1000	1.35	0.8	0.5
MgSO ₄	N/1000	1.55	0.9	0.65
CuSO ₄	N/500	1.0	0.95	0.80
KMnO ₄	N/400	1.10	0.55	0.25

The results in Table VII reveal some very interesting facts on the coagulation of sols. It will be seen that the general dilution rule that the greater the concentration of the sol the greater is the amount of the coagulating ion necessary for coagulation is applicable for the anions Cl⁻ and NO₃⁻, when electrolytes like KCl and KNO₃ are used. On the other hand, the general dilution rule is not applicable to these anions (Cl⁻ and NO₃⁻) when electrolytes like CuCl₂ and AgNO₃ are used. The fact that more of ClCu₂ or AgNO₃ is required to coagulate the dilute sol than a concentrated one, is evidently due to the high preferential adsorption of Ag⁺ and Cu⁺⁺ ions by manganese dioxide.

¹ Compare Chatterji and Dhar: loc. cit.

Adsorption of Positive and Negative Ions of Electrolytes by Manganese Dioxide.

When small amounts of cupric chloride are added to a positively charged manganese dioxide sol it will attract and adsorb the cupric ions because of the chemical affinity of manganese dioxide for cupric ions. If, however, larger quantities of cupric chloride are added, the adsorption of chlorine ions becomes greater than that of cupric ions, and the sol is actually coagulated by a concentrated solution of this electrolyte. Now, I have already shown, that the abnormal behaviour of a sol on dilution towards its coagulation by an electrolyte, is due to the preferential adsorption of similarly charged ions by the sol, and that the ratio of the amount of adsorption of ions bearing the same charge as the sol to that of the ion of opposite charge should increase as the sol is diluted. In Table VIII our results on the adsorption of cupric and chlorine ions by positively charged manganese dioxide sol as well as by freshly precipitated manganese dioxide are recorded:—

TABLE VIII

Adsorption of Cu^{++} and Cl' ions from a solution of CuCl_2 by positively charged manganese dioxide sol.

Concentration of the sol = 0.320 grms. MnO_2 per litre.

Sol A = 20 c.c. of the sol made up to 50 c.c.

Concentration of the sol	Volume = 50 c.c.; Time = 20 hours			R^1
	Original concentration in millimoles	Final concentration in millimoles	Adsorption in millimoles	
A	5.00 Cu^{++}	4.9958 Cu^{++}	0.0042 Cu^{++}	0.092
	10.00 Cl'	4.9544 Cl'	0.0456 Cl'	
A/2	5.00 Cu^{++}	4.9975 Cu^{++}	0.0025 Cu^{++}	0.109
	10.00 Cl'	9.9771 Cl'	0.0229 Cl'	

(The results given are the mean of two experiments).

Hence the ratio of the amount of adsorption of cupric ion to that of chlorine ion is greater with the sol A/2 than that observed with the sol A.

In Table IX the results are given as obtained by us on the adsorption of both cupric ion and chlorine ion from a copper chloride solution by freshly precipitated manganese dioxide prepared after the method of Sarkar and Dhar.¹

TABLE IX

Sample of manganese dioxide contains 74% MnO_2 and 26% water

Amount of the adsorbent in grm.	Volume = 50 c.c.; Time = 20 hours			R
	Original concentration in millimoles	Final concentration in millimoles	Adsorption in millimoles	
1.0	20.00 Cu^{++}	12.47 Cu^{++}	0.3765 Cu^{++}	2.27
	40.00 Cl'	36.68 Cl'	0.1660 Cl'	
0.5	20.00 Cu^{++}	14.71 Cu^{++}	0.2645 Cu^{++}	3.07
	40.00 Cl'	38.34 Cl'	0.0830 Cl'	
0.25	20.00 Cu^{++}	17.06 Cu^{++}	0.1470 Cu^{++}	3.54
	40.00 Cl'	39.17 Cl'	0.0415 Cl'	

R is the ratio of the amounts of adsorption of cupric ion to that of chlorine ion.

¹ Z. anorg. Chem., 121, 135 (1922).

The results on the adsorption of both cation and anion from a copper chloride solution by freshly precipitated manganese dioxide also show, that the ratio of the amounts of adsorption of the cation to that of the anion increases as the amounts of the adsorbent used are decreased. These results are exactly similar to those obtained by us with positively charged manganese dioxide sol, and greatly strengthen our views already discussed in order to explain the abnormal behaviour of many sols on dilution, viz. more of an electrolyte is necessary to coagulate a dilute sol than a concentrated one.

From Table VIII it will be seen that the amount of adsorption of cupric ion by sol A/2 is greater than half the amount of adsorption of the same ion with sol A. This is because, as is well-known, the adsorption of a substance is always greater per unit mass of the adsorbent when smaller amounts of the adsorbent are used. On the other hand, the amount of adsorption of chlorine ions, which is necessarily due to the charge neutralisation of the colloid particles, is exactly halved when the sol is diluted twice.

It has been shown by Chatterji and Dhar that freshly precipitated manganese dioxide mainly adsorbs the cations from electrolytes, leaving the solution acidic. This is because manganese dioxide being acidic in nature attracts and adsorbs the cation from an added electrolyte, leaving the anion in the solution free where it finds its counterpart H^+ ion from water, and, therefore, gives out acid. It is, therefore, obvious that the amount of an acid liberated during the adsorption of an electrolyte by manganese dioxide, measures the excess of anions, which are not adsorbed by it. Hence, if the cations are only adsorbed by manganese dioxide from an added electrolyte, it is expected that the amount of the acid set free will be equivalent to the amount of cations adsorbed. But as a matter of fact, experimental results prove that the amount of the acid set free is less than the amount which is equivalent to the adsorption of cations. This is because, when the electric charge on manganese dioxide has sufficiently increased due to a high preferential adsorption of cations only, the anions which are also present will be attracted due to electrical attraction by the positively charged surface and will be adsorbed. In other words, the number of anions which can remain free in the solution are smaller than the amount which is equivalent to the amount of cations adsorbed. Hence, it is evident that the amount of adsorption of anions can be easily determined by subtracting the amount of the acid actually liberated from the amount of acid equivalent to the amount of cations adsorbed.

In Table X the amount of adsorption of cations by freshly precipitated manganese dioxide has been determined directly and the amount of adsorption of anions has been calculated from the amount of the acid actually set free, when electrolytes like $AgNO_3$, $CuCl_2$, etc., are added to manganese dioxide:—

TABLE X
Adsorption of AgNO_3 and CuCl_2 by manganese dioxide

Initial concentration	Amount of adsorbent in gram.	Amount of cation adsorbed in gram.	Amount of acid liberated per gram.	Amount of anion adsorbed in millimoles per gram.	R
Electrolyte AgNO_3					
2N	0.5	4.256	2.036	2.220	1.917
"	1.0	4.200	1.936	2.264	1.813
"	1.5	4.119	1.332	2.787	1.478
"	2.0	4.097	1.200	2.897	1.414
0.5N	0.5	2.297	1.528	0.769	2.987
"	1.0	2.277	1.251	1.026	2.219
"	1.5	2.259	0.948	1.311	1.723
"	2.0	2.456	1.000	1.456	1.689
Electrolyte CuCl_2					
2N	0.5	1.297	0.480	0.817	1.587
"	1.0	1.284	0.391	0.893	1.438

The results in Table X prove that for the electrolytes AgNO_3 and CuCl_2 the ratio of the amount of adsorption of the cation to that of the anion, increases as the amount of the adsorbent used is decreased. I have already shown that negatively charged manganese dioxide sol behaves normally towards dilution when coagulated by silver nitrate or a cupric salt. On the other hand, positively charged manganese dioxide sol behaves abnormally towards dilution when coagulated by these electrolytes.

Hence the foregoing experimental results on the adsorption of anions and cations by manganese dioxide sol as well as by precipitated manganese dioxide are in line with those obtained with arsenious sulphide and potassium chloride and strongly support our explanation of the abnormal behaviour of sols on dilution towards their coagulation by univalent ions.

Aluminium Hydroxide Sol

The coagulation of aluminium hydroxide sol has been investigated by Gann,¹ Ishizaka,² and Weiser and Middleton.³ The influence of change of concentration of this sol towards its coagulation by various electrolytes has not been studied before and, therefore, this has been investigated by us.

A sol of aluminum hydroxide is prepared by precipitating $\text{Al}(\text{OH})_3$ from a solution of $\text{Al}(\text{NO}_3)_3$ by ammonia at the ordinary temperature and washing the precipitate free of electrolytes by decantation. It is observed that when the washing has been continued sufficiently long, the precipitated aluminium hydroxide gradually passes into the colloidal state and finally a fairly stable but dilute sol of $\text{Al}(\text{OH})_3$ can be obtained. The sol thus obtained is positively charged.

¹ Kolloidchem. Beihefte, **8**, 125 (1916).

² Z. physik. Chem., **83**, 97 (1913).

³ J. Phys. Chem., **24**, 630 (1920).

In Table XI the results are given as obtained by us on the coagulation of aluminium hydroxide sol at different dilutions by various electrolytes:—

TABLE XI

Concentration of the sol = 0.60 gm. Al_2O_3 per litre

Sol A = 2 c.c. of the sol made up to 6 c.c.

Volume = 6 c.c.; Time = 1 hour

Electrolyte	Sol 2A	Amount to coagulate in c.c.	
		Sol A	Sol A/2
KCl N/10	1.75	1.50	1.30
$\text{K}_2\text{C}_2\text{O}_4$ N/400	1.65	1.25	0.80
K_2SO_4 N/400	1.50	0.65	0.45
K_3Cit N/2,000	1.30	0.65	0.30
$\text{K}_3\text{Fe}(\text{CN})_6$ N/2,000	1.80	1.25	0.95
$\text{K}_4\text{Fe}(\text{CN})_6$ N/2,500	1.80	0.90	0.45

The sol being positively charged the anions possess the coagulating effect.

The foregoing results conclusively prove that the greater the concentration of the sol the greater is the amount of an electrolyte necessary to coagulate it irrespective of the valency of the coagulating ion. Similar results have been recently obtained by Sen¹ with a suspension of aluminium hydroxide stabilised by different organic acids.

We have already shown with $\text{Fe}(\text{OH})_3$ sol that it obeys the general dilution rule when coagulated by electrolytes like KCl, K_2SO_4 , $\text{K}_4\text{Fe}(\text{CN})_6$, etc., but behaves abnormally on dilution when coagulated by HCl, FeCl_3 , $\text{Al}(\text{NO}_3)_3$, etc., as appreciable amounts of cations are adsorbed by ferric hydroxide from these electrolytes. It is, therefore, expected that $\text{Al}(\text{OH})_3$ sol, which is also known to adsorb cations from electrolytes like HCl, FeCl_3 , $\text{Al}(\text{NO}_3)_3$, etc., appreciably, should behave abnormally on dilution when coagulated by these electrolytes, but as these electrolytes possess a solvent action and appreciably dissolve $\text{Al}(\text{OH})_3$ sol at their precipitating concentrations the investigations from this point of view could not be pursued.

Vanadium Pentoxide Sol

Vanadium pentoxide sol is prepared after the method of Biltz² and is dialysed for a week, when it is free from hydrochloric acid. The sol is negatively charged. The coagulation of vanadium pentoxide sol has been investigated by Freundlich and Leonhardt³, who have shown that the Schulze-Hardy law is applicable to this sol. In a recent paper Gessner⁴ has studied the behaviour of vanadium pentoxide sol from various points of view, and his results on the precipitation values of NaCl and CaCl_2 for varying concentrations of vanadium pentoxide have been cited by Wiegner⁵ to prove that this

¹ J. Phys. Chem., **28**, 1029 (1924).

² Ber., **37**, 1095 (1904).

³ Kolloidchem. Beihefte, **7**, 195 (1915).

⁴ Kolloidchem. Beihefte, **19**, 213 (1924).

⁵ Kolloid-Z. (Zsigmondy Festschrift), **36**, 341 (1925).

sol becomes stable on dilution towards an univalent electrolyte like NaCl. Gessner has, however, used different samples of vanadium pentoxide sol in his experiments on the coagulation of this sol at different concentrations. Hence it is apparent that no definite conclusion can be drawn from the experiments of Gessner on the stability of the sol on dilution, for it is well-known that the coagulating power of an electrolyte is dependent on the mode of the preparation of a sol and it is different for different samples of a sol obtained from the same substance.

In Table XII our results are given with the same sample of the sol and shows the influence of change of concentration towards its coagulation by various electrolytes:—

TABLE XII

Concentration of vanadium pentoxide sol = 0.92 grm. V_2O_5 per litre

Sol A = 2 c.c. of the sol made up to 6 c.c.

Volume = 6 c.c.; Time = $\frac{1}{2}$ hour

Electrolyte	Sol A	Amount to coagulate in c.c.	
		Sol A/2	Sol A/4
KCl N/10	0.80	0.80	0.70
NaCl N/10	2.05	1.90	1.85
BaCl ₂ N/500	1.20	1.00	0.75
Al(NO ₃) ₃ N/1,000	1.80	0.95	0.55

The foregoing results are not in line with the conclusions of Wiegner, and prove that the general dilution rule is obeyed by this sol and more of an electrolyte is required to coagulate a concentrated sol than a dilute one irrespective of the valency of the coagulating ion.

We have observed that vanadium pentoxide sol appreciably adsorbs a cation from the coagulating electrolyte leaving the filtrate acid.

Thorium Hydroxide Sol

The sol is prepared after the method of Biltz, which consists in dialysing a solution of thorium nitrate. The thorium nitrate solution is dialysed for a week in a parchment bag, when the sol of thorium hydroxide formed by hydrolysis of the salt is practically free from electrolytes. The sol thus formed is, however, very stable and could not be coagulated by even 3N KCl. The sol is, however, easily coagulated by a solution of KBrO₃.

Table XIII results are given when this sol is coagulated at different dilutions by various electrolytes:—

TABLE XIII

Concentration of the sol = 1.36 grams. ThO₂ per litre

Sol A = 2 c.c. of the sol made up to 6 c.c.

Volume = 6 c.c.; Time = $\frac{1}{2}$ hour

Electrolyte		Amount to coagulate in c.c.		
		Sol 3A/2	Sol A	Sol A/2
KBrO ₃	N/2.4	2.80	2.60	2.10
K ₂ SO ₄	N/500	3.0	2.40	1.65
K ₄ Fe(CN) ₆	N/1,000	3.60	2.70	1.40

The results in Table XIII show that thorium hydroxide sol behaves normally on dilution, when coagulated by monovalent, bivalent or polyvalent anions. The sol being positively charged the anions possess the coagulating effect.

Prussian Blue Sol

In a previous paper we have investigated the influence of dilution of prussian blue sol on its coagulation by electrolytes and we have found that the sol behaves abnormally toward dilution when coagulated by KCl. Weiser and Nicholas have, however, reported that this sol behaves normally towards dilution when coagulated by KCl. Our sol was completely free from $K_4Fe(CN)_6$, whilst the sol used by Weiser and Nicholas contained some free $K_4Fe(CN)_6$. We have, therefore, made some experiments on the coagulation of prussian blue sol with KCl in the presence of $K_4Fe(CN)_6$. The results are given in Table XIV.

TABLE XIV

Concentration of the sol = 2.76 grms. prussian blue per litre

Sol A = 1 c.c. made up to 10 c.c.

Volume = 10 c.c.; Time = 20 hours

Concentration of the sol	Amount of $K_4Fe(ON)_6N/2$ added in c.c.	Amount of KClN/4. to coagulate in c.c.
A	0.50	2.6
A/2	0.25	3.1
A/5	0.10	3.5

It is obvious from Table XIV that more abnormality towards dilution is observed with prussian blue sol when coagulated by KCl in the presence of $K_4Fe(CN)_6$. These results are very interesting and will be discussed in a subsequent paper.

Uranium Ferrocyanide Sol

This sol has never been studied before. We have prepared the sol of uranium ferrocyanide and have studied its coagulation for the first time.

The coagulation of negatively charged uranium ferrocyanide sol by different electrolytes has been determined at various dilutions of the sol. The most simple method for the preparation of colloidal ferrocyanide is to pour a dilute solution of an uranium salt into a solution of potassium ferrocyanide. Colloidal uranium ferrocyanide for these experiments has been prepared by pouring a dilute solution of uranium nitrate into a dilute solution of potassium ferrocyanide. The hydrosol thus formed is clear and has a deep red colour peculiar to uranium ferrocyanide. With increasing concentration of the uranium nitrate solution the sol becomes more and more turbid and finally coagulates. Colloidal uranium ferrocyanide thus obtained is dialysed for about 12 days when the wash water does not show any test for the ferrocyanide ion. The dialysed sol contains appreciable amount of ferrocyanide which can be easily detected by coagulating the sol and testing for ferrocyanide ion. As this sol has not been studied before, we have made experiments to find out whether this sol follows the Schulze-Hardy law or not. Table XV gives the results:—

TABLE XV

Concentration of the sol = 2.15 grams of uranium ferrocyanide per litre
 3 c.c. of the sol is made up to 10 c.c. on mixing with the electrolyte;
 Time = 2 hours

Electrolyte	Concentration	Amount added in c.c.	Precipitating concentration
KCl	N	2.6	0.2600
K ₂ SO ₄	N	2.9	0.2900
K ₄ Fe(CN) ₆	2N	1.65	0.3300
BaCl ₂	N/25	1.50	0.0060
MgCl ₂	N/25	1.95	0.0078
Al(NO ₃) ₃	N/100	0.85	0.0085
Th(NO ₃) ₄	N/200	1.40	0.0070

An examination of Table XV gives the following order for the precipitation values, beginning with the highest one:

K₄Fe(CN)₆ > K₂SO₄ > KCl > MgCl₂ > BaCl₂ > Al(NO₃)₃ > Th(NO₃)₄.

From this order it appears that the Schulze-Hardy law is applicable to this sol. The results of Pappadà on the coagulation of prussian blue sol and colloidal copper ferrocyanide show that the Schulze-Hardy law is also applicable to these sols.

It has been already reported that prussian blue sol behaves abnormally on dilution when coagulated by potassium chloride. Similar results have been obtained by Sen and Mehrotra¹ with a sol of copper ferrocyanide.

In Table XVI the results are given on the influence of dilution of uranium Ferrocyanide sol towards its coagulation by various electrolytes:

TABLE XVI

Concentration of the sol = 2.15 grams of uranium ferrocyanide per litre
 Sol A = 3 c.c. sol made up to 10 c.c.
 Volume = 10 c.c.; Time = 2 hours

Electrolyte	Amount to coagulate in c.c.		
	Sol 2A	Sol A	Sol A/3
KCl N	2.60	2.60	2.50
K ₂ Fe(CN) ₆ N	2.90	2.90	3.00
K ₄ Fe(CN) ₆ 2N	1.40	1.65	1.85
BaCl ₂ N/25	1.70	1.50	1.30
Al(NO ₃) ₃ N/100	1.80	0.85	0.35
Th(NO ₃) ₄ N/200	2.85	1.40	0.55

It will be seen from these results that the amount of KCl or K₂SO₄ required to coagulate a dilute or a concentrated sol is practically constant, whilst a definite abnormality is observed with potassium ferrocyanide, that is, more of this electrolyte is necessary to coagulate a dilute sol than a concentrated one.

¹ Z. anorg. Chem., **142**, 345 (1925).

It is well-known that colloidal ferrocyanides are stabilised by the preferential adsorption of the ferrocyanide ion. I have observed that a hydrosol of uranium ferrocyanide is only stable when there is an excess of potassium ferrocyanide. A small excess of uranium nitrate causes complete coagulation of the sol. Potassium ferrocyanide in large excess coagulates the sol, because as the concentration of this electrolyte is gradually increased the adsorption of this electrolyte is gradually increased the adsorption of ferrocyanide ion reaches a maximum and finally the influence of the oppositely charged potassium ion becomes prominent and coagulates the sol.

We have observed that on shaking a well washed precipitate of uranium ferrocyanide with a dilute solution of potassium ferrocyanide traces of alkali are set free, probably due to the preferential adsorption of ferrocyanide ions. Duclaux¹ has shown that a great deal of potassium ferrocyanide is also taken up when copper ferrocyanide is precipitated, and that it is practically impossible to free cupric ferrocyanide from adsorbed potassium ferrocyanide. Duclaux, however, believes that potassium ferrocyanide is chemically combined with cupric ferrocyanide. In a recent paper Frankfort and Wilkinson² have found that alkalinity is developed when cupric ferrocyanide is shaken with $K_4Fe(CN)_6$. Working with two grams of cupric ferrocyanide and 2N $K_4Fe(CN)_6$ solution they observed a total alkalinity of 200 c.c. of 0.01N KOH. On the addition of more concentrated solution of $K_4Fe(CN)_6$ the amount of alkali gradually decreased and finally the mixture became slightly acid. The development of the alkalinity is certainly due to the preferential adsorption of $Fe(CN)'''_6$ ion by cupric ferrocyanide, leaving its counterpart K^+ ion free, so that an excess of negative ion OH^- must be found for maintaining electric neutrality of the solution. If, however, the amount of potassium ferrocyanide added is gradually increased, the preferential adsorption of ferrocyanide ion reaches a maximum, and on the continued addition of $K_4Fe(CN)_6$ the potassium ions, which are also present, become effective in coagulating the negatively charged sol with the liberation of an acid. We have observed that appreciable amounts of UO_2^{++} ions are adsorbed by uranium ferrocyanide and an appreciable amount of acid is developed when either a sol of uranium ferrocyanide is coagulated with uranium nitrate or a pure sample of uranium ferrocyanide is shaken with a solution of uranium nitrate. All attempts to prepare a positively charged sol of uranium ferrocyanide by the preferential adsorption of uranium ions, however, failed.

Gum Dammar Sol

The sol of this resinous substance is prepared exactly in the same way as the mastic sol. The resinous mass is powdered and dissolved in alcohol and the colloidal solution is obtained by pouring this alcoholic solution in a large volume of water. As gum dammar sol has not been investigated before, we have studied the coagulation of this sol by various electrolytes to find out if the Schulze-Hardy law is applicable to this sol.

¹ J. Chim. phys., 7, 405 (1909).

² J. Phys. Chem., 28, 651 (1924).

In Table XVII our results are reproduced:—

TABLE XVII

Concentration of the sol¹ = 0.87 grm. gum dammar per litre
2 c.c. of the sol made up to 10 c.c.
Volume = 10 c.c.; Time = 1 hour

Electrolyte	Concentration	Amount added in c.c.	Precipitating concentration
KCl	N/2	2.65	0.1325
KNO ₃	N/2	2.40	0.1200
K ₂ SO ₄	N/2	2.80	0.1400
NaCl	N/2	2.80	0.1400
CH ₃ COONa	2N	1.25	0.2500
NH ₄ Cl	N/2	1.30	0.0650
HCl	N/100	0.80	0.0008
HNO ₃	N/100	0.80	0.0008
BaCl ₂	N/10	1.30	0.0130
SrCl ₂	N/10	1.30	0.0130
Al(NO ₃) ₃	N/2,000	1.80	0.00009

An examination of Table XVII gives the following order of precipitation values for different electrolytes beginning with the highest one:—

CH₃COONa > K₂SO₄, NaCl > KCl > KNO₃ > NH₄Cl > BaCl₂, SrCl₂ > HCl, HNO₃ > Al(NO₃)₃. This shows that the Schulze-Hardy law is followed only partially, the exception being the H⁺ ions, which possess greater coagulating power than bivalent Ba⁺⁺ or Sr⁺⁺ ions. Similar results are obtained on the coagulation of mastic sol, H⁺ ions possessing greater coagulating power than bivalent Ba⁺⁺ or Ca⁺⁺ ions.² We have shown in a previous paper that this peculiar behaviour of hydrogen ions is due to the hydrolysis of sols of resinous substances like mastic, (gum dammar, gamboge etc. We have observed that the negatively charged gum dammar sol takes up a positive charge if quantities of Al(NO₃)₃ greater than its precipitating concentration are added all at once to this sol.

TABLE XVIII

Concentration of gum dammar sol = 0.87 grm. per litre
Sol A = 4 c.c. of the sol made up to 10 c.c.
Volume = 10 c.c.; Time = 1 hour

Electrolyte		Sol A	Amount to coagulate in c.c. Sol A/2	Sol A/4
CH ₃ COONa	2N	1.25	1.40	1.80
KCl	N/2	2.00	2.65	3.00
KNO ₃	N/2	—	2.40	2.70
BaCl ₂	N/10	1.10	1.30	1.40
Al(NO ₃) ₃	N/2,000	2.50	1.80	1.30

¹ The concentration of the sol has been estimated by evaporating a known volume of the sol on a water-bath in a platinum crucible.

² Compare Freundlich: "Kapillarchemie," 367 (1909).

In Table XVIII the results showing the influence of change of concentration of gum dammar sol towards its coagulation by various electrolytes are recorded.

These results are similar to those obtained by us with mastic sol when coagulated at various concentrations and this sol behaves abnormally on dilution when coagulated by both univalent and bivalent cations. It is interesting to observe here that when arsenious sulphide and antimony sulphide sols are coagulated with bivalent cations like Ba^{++} , Mg^{++} , etc., the amounts of these cations required to coagulate a dilute or a concentrated sol are practically constant. Our results in Table XVIII are unlike those obtained with arsenious and antimony sulphide sols and show that the sols of gum dammar and of mastic are not only abnormal on dilution towards monovalent electrolytes like KCl , KNO_3 , etc., but are also abnormal towards bivalent electrolytes like BaCl_2 , SrCl_2 , etc. The abnormality on dilution is more marked when the sol of gum dammar is coagulated by KCl or KNO_3 than that observed when it is coagulated by BaCl_2 . Greater amounts of $\text{Al}(\text{NO}_3)_3$ are, however, required to coagulate a concentrated sol than a dilute one and the general dilution rule is applicable to the coagulation of this sol by aluminium nitrate.

Gamboge Sol

This sol has been studied because it closely resembles the sols of mastic and gum dammar in its chemical properties. The sol has been prepared by the same method as that adopted in the preparation of the sols of mastic and gum dammar.

In Table XIX the results are given as obtained by us when gamboge sol is coagulated at different dilutions by various electrolytes:—

TABLE XIX

Concentration of the sol = 0.388 gm. gamboge per litre

Sol A = 5 c.c. of the sol made up to 10 c.c.

Volume = 10 c.c.; Time = 1 hour

Electrolyte		Sol A	Amount to coagulate in c.c.	
			Sol A/2	Sol A/4
KCl	2N	0.90	1.80	2.40
BaCl ₂	N/5	0.90	0.90	0.95
Al(NO ₃) ₃	N/2,000	0.95	0.50	0.45

These results prove that gamboge sol behaves abnormally on dilution when coagulated by either KCl or BaCl_2 , whilst it behaves normally on dilution when coagulated by aluminium nitrate. Gamboge sol, therefore, behaves exactly like mastic and gum dammar sols on dilution when coagulated by various electrolytes.

Sulphur Sol (Weimarn)

Odén¹ has studied the coagulation of colloidal sulphur prepared by the action of an acid on a sodium thiosulphate solution. His results show that the Schulze-Hardy law fails in this case, a few univalent ions possess greater coagulating powers than many bivalent ions. Odén has also investigated the influence of dilution on the stability of this sol towards many electrolytes and his data show that whilst the sol behaves as a more stable one and requires greater quantities of an univalent coagulating ion to precipitate a dilute sol than a concentrated one, the amount of bivalent and trivalent ions required to coagulate the sol decreases with the decreasing concentration of the sol. Colloidal sulphur prepared by Weimarn's method shows less deviations from the Schulze-Hardy law,² and as the influence of concentration of this sol towards its coagulation has not been studied, we have taken up this problem.

The sol was prepared by dissolving γ -sulphur in alcohol and pouring the alcoholic solution into a large volume of water. The sol is extremely unstable and coagulation begins in the sol when kept for more than a week.

The experimental results, given in Table XX, were obtained with a Weimarn sulphur sol and the coagulation experiments were carried on the same day as the sol was prepared.

TABLE XX

Sol A = 4 c.c. of the original sol made up to 8 c.c.

Volume = 8 c.c.; Time = $\frac{1}{2}$ hour

Concentration of the sol.	KCl N/2 added in c.c.	BaCl ₂ N/25 added in c.c.
A	1.0	1.05
A/2	0.85	0.5
A/4	0.70	0.2

From the above results it is obvious that less of monovalent and bivalent electrolytes are necessary to coagulate the dilute sol than a concentrated one. The data are not very accurate as it is very difficult to obtain exactly reproducible results.

Gold Sol

Coagulation of this sol has been investigated by several workers³ in this field. Recently Freundlich and Scholz⁴ have studied the coagulation of the sol with a mixture of electrolytes of widely varying valencies. Their sol was prepared according to the method of Donau⁵ by reducing HAuCl_4 to metallic gold by carbon monoxide. The influence of change of concentration of gold sol on its coagulation has not been studied before, and it was, therefore, considered desirable to investigate this problem.

¹ "Der kolloide Schwefel," 156 (1912).

² Compare Freundlich: "Kapillarchemie," 849 (1922).

³ Compare Freundlich: "Kapillarchemie," 576 (1923).

⁴ Kolloidchem. Beihefte, 16, 267 (1922).

⁵ Monatsheft, 26, 525 (1905).

The sol was prepared according to the method of Zsigmondy¹ by reducing a solution of HAuCl_4 with formaldehyde in presence of small quantities of K_2CO_3 . In Table XXI the results are recorded as obtained when gold sol is coagulated at different concentrations by various electrolytes:

TABLE XXI

Concentration of the sol = 0.065 gm. gold per litre

Sol A = 4 c.c. of the sol made up to 6 c.c.

Volume = 6 c.c.; Time = 1 hour

Electrolyte		Sol A	Amount to coagulate in c.c.	
			Sol 3A/4	Sol A/2
KCl	N/5	2.00	1.80	1.65
KNO_3	N/5	2.10	1.90	1.80
KOH	N/2	2.00	1.90	2.00
$\text{K}_2\text{C}_2\text{O}_4$	N/2	1.65	1.70	1.70
BaCl_2	N/50	1.00	0.90	0.75
$\text{Al}(\text{NO}_3)_3$	N/1,000	0.80	0.55	0.35

Table XXI shows that greater amounts of KCl, KNO_3 , BaCl_2 and $\text{Al}(\text{NO}_3)_3$ are required to coagulate a concentrated gold sol than a dilute one, and, therefore, obeys the general dilution rule. On the other hand, when gold sol is coagulated with either KOH or $\text{K}_2\text{C}_2\text{O}_4$ the quantities of these electrolytes required to coagulate a dilute or a concentrated sol are practically constant and have a tendency to behave abnormally towards dilution when coagulated by KOH and $\text{K}_2\text{C}_2\text{O}_4$. These results are very interesting and prove that the abnormality of gold sol on dilution towards its coagulation by KOH and $\text{K}_2\text{C}_2\text{O}_4$ is certainly due to the adsorption of anions from these electrolytes and its consequent stabilisation by this adsorption of ions carrying the same charge as the sol.

In Table XXII the precipitation values of various potassium compounds determined for Sol A are given:—

TABLE XXII

Electrolyte	Concentration	Amount added in c.c.	Precipitation value
KCl	N/5	2.00	0.0667
KNO_3	N/5	2.10	0.0700
KOH	N/2	2.00	0.1667
$\text{K}_2\text{C}_2\text{O}_4$	N/2	1.65	0.1375

The precipitation values of the potassium compounds investigated are in the order $\text{KOH} > \text{K}_2\text{C}_2\text{O}_4 > \text{KNO}_3 > \text{KCl}$, beginning with the electrolyte possessing the highest precipitation value. The great difference in the precipitation values of either $\text{K}_2\text{C}_2\text{O}_4$ or KOH from those of KCl or KNO_3 is obviously due to the greater amount of adsorption of OH' or $\text{C}_2\text{O}_4''$ ions than that of Cl' or NO_3' . This conclusion has been further substantiated by our researches on the coagulation of this sol with a mixture of electrolytes and on the phenomenon of acclimatization.

In a recent paper Morris and Harris¹ have also emphasised the marked influence of anions on the coagulation of gold sol and from their experiments on the coagulating power of several sodium salts, they have obtained the following order showing the influence of anions on its coagulation:— $C_2O_4'' > HPO_4'' > CO_3'' > OH'$, citrate''' $> HCO_3' > Br' > I'$, acetate' $> valerate' > butyrate'$, CNS' $> SO_4'' > Cl' > benzoate'$.

The above order proves conclusively that C_2O_4'' and OH' ions possess far greater stabilising influence on the coagulation of gold sol than that of Cl' ions. These results of Morris and Harris are, therefore, in line with the results obtained by us on the coagulation of gold sol.

Silver Sol

The sol was prepared according to the method of Kohlschütter² by reducing a solution of Ag_2O in a current of hydrogen at 60° . The sol thus obtained, however, contains enough of OH' ions as an impurity and it is practically impossible to reduce Ag_2O completely by this method.

The experimental results on the coagulation of this sol at different concentrations by various electrolytes are given in Table XXIII.

TABLE XXIII

Concentration of the sol = 0.18 grm. Ag per litre

Sol A = 4 c.c. of the original sol made up to 6 c.c.

Volume = 6 c.c.; Time = 1 hour

Electrolyte		Amount to coagulate in c.c.		
		Sol A	Sol 3A/4	Sol A/2
NaOH	N/5	1.20	2.05	2.80
KNO ₃	N/8	1.90	2.10	2.10
Ba(NO ₃) ₂	N/625	1.80	1.75	1.75
Al(NO ₃) ₃	N/5,000	1.40	1.30	0.95

The foregoing results show that the sol behaves abnormally towards dilution when it is coagulated with either KNO_3 or $NaOH$, but the abnormality is far more developed with $NaOH$ than with KNO_3 . This is certainly due to the fact that OH' ions possess a great stabilising influence on this sol. On the other hand, practically constant amounts of $Ba(NO_3)_2$ are required to coagulate a concentrated or a dilute sol, and with $Al(NO_3)_3$ the general dilution rule that the greater the concentration of the sol the greater is the amount of an electrolyte necessary for coagulation is obeyed.

It will be interesting to point out here that the silver sol obtained by Kohlschütter's method is by no means pure. In a very recent paper Erlach and Pauli³ have shown that this sol even on dialysis contains varying quantities of silver hydroxide, some times as much as twenty per cent. The considerable amount of OH' ions available from silver hydroxide possess a great

¹ Trans. Faraday Soc., 25, 30 (1924).

² Z. Elektrochem., 14, 49 (1908).

³ Kolloid-Z., 34, 213 (1924).

stabilising influence and it is, therefore, difficult to draw any definite conclusion about the adsorption of NO_3^- ion from either KNO_3 or $\text{Ba}(\text{NO}_3)_2$. The influence of OH^- ions will be discussed in a subsequent paper.

Summary and Conclusion

From the experimental results advanced in the foregoing pages, it will be seen that the following sols follow the general dilution rule, viz., the greater the concentration of the sol the greater is the amount of an electrolyte necessary for coagulation: (1) stannic hydroxide (positive); (2) manganese dioxide (negative); (3) manganese dioxide (positive); (4) aluminium hydroxide; (5) vanadium pentoxide; (6) thorium hydroxide; (7) sulphur (Weimarn); and (8) gold.

The following sols do not follow the general dilution rule and hence behave abnormally, when coagulated by univalent and sometimes by bivalent ions: (1) antimony sulphide; (2) prussian blue; (3) gum dammar; and (4) gamboge.

Uranium ferrocyanide sol is practically on the border line. A sol of metallic silver is abnormal towards dilution when coagulated by univalent electrolytes because it is usually associated with silver hydroxide of which OH^- ions are highly adsorbed by a sol of silver.

We have proved in the foregoing pages that when positively charged manganese dioxide sol is coagulated by AgNO_3 or CuCl_2 , the sol requires more of these electrolyte to coagulate it in the diluted condition than that required to coagulate the concentrated one. This abnormal behaviour is certainly associated with the marked adsorption of Ag or Cu ions by manganese dioxide.

From the foregoing results it will be clear that those sols, which do not adsorb an ion carrying the same charge as the sol, follow the general dilution rule, whilst those sols, which are capable of adsorbing an ion carrying the same charge as the sol are normal. Hence from our experimental researches it will be clear that the adsorption of an ion carrying the same charge as the sol plays a very important part in the coagulation of sols.

In previous papers published from this laboratory it has been proved that sols like arsenious sulphide, antimony sulphide, mastic, gamboge, gum dammar, prussian blue, copper ferrocyanide etc. are appreciably hydrolysed in presence of water and this hydrolysis makes these sols stable towards electrolytes. It is well known that the degree of hydrolysis of a substance increases with dilution; consequently, these sols become more stable towards electrolytes because of increased hydrolysis. We have also shown that hydrogen ions check the hydrolysis of these sols, which behave abnormally when coagulated by KCl , LiCl , etc., but all these sols have a tendency to behave normally when coagulated by acids, which check the hydrolysis of the sols considerably and make them unstable towards electrolytes.

DYNAMIC SURFACE TENSION AND THE STRUCTURE OF SURFACES

BY OSCAR KNEFLER RICE

Sudden extension or contraction of a surface may affect the instantaneous value of the surface tension in two ways. In the first place it may do so by causing a change in the temperature at the surface, Gibbs¹ having shown that this will always result in an increase in tension on expansion and a decrease on contraction. If there are two or more components the surface tension may be affected because of the slowness of establishment of equilibrium due to the slowness with which substances in the solution diffuse to the surface. The latter effect should be the more important one, as thermal equilibrium is undoubtedly established much more quickly. This case has also been discussed by Gibbs², as follows. Since the substances which diminish surface tension tend to be adsorbed at the surface, sudden expansion of the surface will leave the solution near the surface poorer in these substances. There will therefore be an increase of surface tension if we can assume that the general character of the results is to be given by supposing that equilibrium is established at the surface and some little way back, but not throughout the solution. Contraction, on the other hand, by creating an excess of the substances which diminish surface tension in the neighborhood of the surface, will cause a decrease of surface tension.

But we may still inquire as to just what would happen if the surface were so rapidly extended that partial equilibrium were very far from being established. We may gain some information on this subject by looking at the matter from a molecular kinetic point of view. The molecules which tend to crowd to the surface are the ones on which the intermolecular attractive forces are the least. But the surface tension, according to Laplace and van der Waals, depends on the molecular forces at the surface, and these will be least when as many as possible of the weakly attracted molecules have had time to get to the surface. Very rapid contraction, on the same basis, will cause a decrease of the surface tension, as there will be too many of the weakly attracted molecules near the surface. This, however, is not very rigorous, and does not help us if, for example, we wish to consider the case of a pure liquid in which the molecules are normally oriented, but whose surface is extended so rapidly as to allow no time for orientation³. It is true, of course, that orientation would probably take place even faster than thermal equilibrium would be established, so the effect would be masked and unobservable, but we can at least consider it in theory.

¹ Gibbs: "Scientific Papers," 1, 269 (1906).

² Gibbs: *loc. cit.*, p. 272.

³ Such an effect must not be confused with that due to the presence of several different species of molecules, arising from association, in a pure liquid. See Lenard: *Sitzungber. Heidelberger Akad.*, 1910, 18; see also Bancroft: "Applied Colloid Chemistry," p. 134 (1921), on the effect of a surface transition layer.

We may avoid all difficulties by a single thermodynamic proof, which covers every situation, apart from the thermal effects, and which, in spite of its simplicity, is not, to my knowledge, to be found in the literature.

Relation between Dynamic and Static Surface Tensions

Suppose that we start with a body of liquid and very rapidly increase its surface by unity, so that no time is allowed for equilibrium to be established at the surface. The process under these conditions is nevertheless reversible, and the free energy change is therefore given by γ' , the instantaneous value of the surface tension, or, as we shall call it, the dynamic surface tension of extension. Now let the surface come to equilibrium with a change of free energy, a , which must be negative. Now change the surface back to its original size reversibly and slowly, the change in free energy being γ the ordinary, or static, surface tension. The system is then back to its original condition, and the change of free energy in the cycle must have been zero, or

$$\gamma' - \gamma + a = 0 \quad (1)$$

Hence

$$\gamma' > \gamma \quad (1a)$$

as a is negative.

Now in a similar manner, by first increasing the surface slowly, then decreasing it rapidly, and then allowing equilibrium to be established by diffusion, we show that the dynamic surface tension of contraction is less than the static surface tension.

In what follows we shall not have any occasion to deal with the dynamic surface tension of contraction, and we shall refer to that of extension simply as the dynamic surface tension.

In some cases the dynamic surface tension may be measured by a method which does not actually bring about an extension of the surface, but which by providing fresh surface affects the composition in the neighborhood of the surface in the way extension would affect it. The surface tension resulting from such a process is the same as the dynamic surface tension of extension (aside from thermal effects).

Review of the Literature

Any experimental data that one can bring to bear on the subject is unsatisfactory. There have been numerous determinations of surface tensions by various methods, many of them giving contradictory results; besides there is always the difficulty in deciding whether a method will give dynamic or static surface tension. In no case, I believe, has a method been used which would give dynamic surface tension of contraction. The following account is to be considered merely as illustrative of what may be found in the literature.

One means of getting a fresh surface is the use of an oscillating jet. This was first used by Rayleigh, and a summary of his results is given by Freundlich¹ and by Bancroft², together with measurements of the same solutions by a

¹ Freundlich: "Kapillarchemie," 735 (1922).

² Bancroft: *loc. cit.*, p. 132.

static method. Using sodium oleate and saponine solutions, he found in every case that the dynamic surface tension was considerably greater than the static. He detected no difference between the dynamic and static surface tensions of water.

Bohr¹ measured the surface tension of water by this method, getting 72.35 dynes per cm. (corrected to 18°C.) against the static value of about 72.9. Stocker², using this method, got a value of 72.51 for water at 18°C. He also measured some surface tensions of salt solutions, the results usually being about a half dyne low, but in some cases being about a dyne below the static values. These results are contrary to our expectation³. Lenard⁴ has stated his belief that the dynamic value should be higher, and he notes that when Bohr and others measure nearer the orifice their values exceed that of the ordinary static surface tension, which he explains as being due to the fact that the surface near the orifice is fresher, but which Bohr would say was due to hydrodynamical disturbances.

We may also mention the experiments done by Pedersen⁵ by this method. He finds for water at 15°C. the value 74.30, which is high. He finds for toluene at 15° the value 28.76, agreeing with Volkmann's result of 28.79 by the capillary rise method, but for aniline he gets 43.00 as contrasted with Volkmann's 44.30, and Feustal's 46.6 (which was done by the method of maximum pressure in small bubbles).

It is well known that fresh mercury surfaces in the presence of gases have a higher surface tension than old ones.⁶

Grünmach⁷ using a capillary ripple method, which does not however seem to be a very satisfactory way, finds that alcohol in which the surface is being continually renewed has a surface tension nearly seven dynes lower with an old surface, and similar, but not such marked differences with water.

Hiss⁸ used a capillary rise method for determining surface tension. In every case but one Hiss found the dynamic to be higher than the static surface tension, and in this one case he concluded that the two were equal, but it must be noted that if the dynamic were lower he would not have found it by his method.

Case where Equilibrium is established for the Solvent but not for the Solute

Hiss's experiments are valuable in that they give an idea of the actual variation of the surface tension with the time. His experiments on soap solutions showed that the time required for the final value of the tension to be reached was considerably greater than was the case for pure water. It may

¹ Bohr: Phil. Trans., 209 A, 281 (1909).

² Z. physik. Chem., 94, 149 (1920).

³ No significance can be attached to the comparison of measurements on ammonia solutions given by Stocker, due to the high vapor pressure of ammonia from these solutions.

⁴ Lenard: loc. cit.

⁵ Pedersen: Phil. Trans., 207 A, 381 (1908).

⁸ Hiss: Diss. Heidelberg (1913).

thus be possible to study dynamic surface tensions when the surface is of such an age that for pure water at that age the surface tension would have its static value. In this case the difference in the dynamic and static surface tension would be attributed to the solute alone. This was likely the case, at least in part, in Rayleigh's experiments, and in some done by du Noüy¹ with very dilute sodium oleate solutions for which he found it required some hours to get the static surface tension.

In view of this it may be of some interest to develop a theory for the dynamic surface tension when it is assumed that equilibrium is established as far as solvent is concerned, but not established at all with respect to solute.

Now we can see offhand that the more the adsorption is confined to a narrow region of the liquid near the surface the greater the difference in the dynamic and static surface tensions will be; for the higher the concentration (or the lower, if the adsorption is negative) of the solute in that region will be for a given amount of material adsorbed, and therefore the greater the change in concentration and hence in free energy when equilibrium is established after a rapid increase of surface. (The concentration of the solvent does not concern us, as equilibrium is attained for it.) We will develop this idea from a more mathematical point of view later, and get some idea as to the magnitude of the effect.

We may also note that the more adsorption is confined to a narrow region the more slowly we should expect equilibrium to be established. There are, therefore, two reasons for the difference in dynamic and static surface tension to be particularly noticeable if the adsorption is so confined, one being a thermodynamic one and the other depending on a rate of diffusion.

We will now proceed to the mathematical development, under the assumption that there is no change in volume in any of our processes. Our method of attack will consist in an evaluation of the quantity a in equation (1).

We will let n be the concentration of the dissolved material in the solution far from the surface, and n_x its concentration at a distance x from the surface. If u is the amount of adsorption per unit surface, then $u = \int_0^\infty (n_x - n) dx$.

We will consider a cycle of operations which take place at a certain definite concentration, and we will carry on our processes in such a way that $n_x - n/u$ is a function of x and n only, not a function of u . That is, while the amount of substance adsorbed may vary, its distribution never is allowed to, for it will be seen that $(n_x - n)/u$ indicates the relative amount of adsorption at the point x .

Let \bar{F} be the partial free energy of the solute in the solution, \bar{F}_x the partial free energy at a distance x from the surface (i.e., the free energy of transfer of unit amount of solute from the corresponding point in a solution whose n_x is unity to the proper point in the given solution), and ΔF_x the free energy of transfer from an infinite distance in the solution to the point in question when both n and n_x are equal to unity. Let γ and γ' have the previously assigned meanings.

¹ Du Noüy: Compt. rend., 178, 1102 (1924).

As stated, our proposition is now to evaluate a in terms of these quantities. In the case we are considering a is the free energy change which takes place when equilibrium is established after the surface has been very rapidly extended, or the free energy of transfer of a certain amount of material from the interior of the solution to its proper place at the surface (or from the surface to the interior, in which case we give it a negative value). We assume the system to be so extensive that the concentration in the interior of the solution is not appreciably affected by such a transfer.

Now if we bring a certain amount of the solute, du , to unit area of the surface, the part which lies between x and $x + dx$ receives an amount $(n_x - n) dx$. As we are going to effect this transfer in such a manner that $(n_x - n)/u$ is a constant and equal to $(n_{x1} - n)/u_1$, where n_{x1} and u_1 are the values which are finally going to be assumed when equilibrium is reached, we have

$$n_x - n = \frac{n_{x1} - n}{u_1} u \text{ or } d(n_x - n) = \frac{n_{x1} - n}{u_1} du$$

In order to effect this transfer there was a change of free energy equal to $(-\bar{F} + \Delta F_x + \bar{F}_x) \frac{n_{x1} - n}{u_1} dx du$ and integrating over the entire surface layer, and over the entire period of adsorption in which u varies from 0 to u_1 , we get

$$a = \int_0^{u_1} \int_0^\infty (-\bar{F} + \Delta F_x + \bar{F}_x) \left(\frac{n_{x1} - n}{u_1} \right) dx du \quad (2)$$

Now if we remember that \bar{F} is independent of both u and x and that $\int_0^\infty (n_{x1} - n) dx = u_1$, we may perform part of the integration indicated in (2), getting

$$a = \int_0^{u_1} \int_0^\infty (\Delta F_x + \bar{F}_x) \left(\frac{n_{x1} - n}{u_1} \right) dx du + \bar{F} u_1 \quad (3)$$

Now if we put (3) in equation (1) this will give us the equation we have been striving to obtain.

We may get more information however if we first differentiate (1) with respect to n as independent variable under the condition that equilibrium be everywhere maintained between the surface and the interior of the solution. This gives us

$$\frac{d\gamma'}{dn} = \frac{d\gamma}{dn} - \left(\frac{\partial a}{\partial n} \right)_{u_1} - \left(\frac{\partial a}{\partial u_1} \right)_n \frac{du_1}{dn} \quad (4)$$

Now we will use (2) in the evaluation of $(\partial a / \partial u_1)_n$ and (3) in the evaluation of $(\partial a / \partial n)_{u_1}$. In doing this we must remember that $\left[\frac{\partial}{\partial n} \left(\frac{n_{x1} - n}{u_1} \right) \right]_{x, u_1}$ will not in general be zero, but $\left[\frac{\partial}{\partial u_1} \left(\frac{n_{x1} - n}{u_1} \right) \right]_{x, n}$ will. When we differentiate

partially with respect to u_1 we do so holding the distribution of solute at the surface constant, and it amounts to differentiation with respect to the upper limit. The partial differentiation with respect to n is to take into account the effect of any change in distribution at the surface. Thus (4) becomes

$$\begin{aligned} \frac{d\gamma'}{dn} = \frac{d\gamma}{dn} - \frac{\partial}{\partial n} \left[\int_0^{u_1} \int_0^\infty (F_x + \Delta F_x) \left(\frac{n_{x1} - n}{u_1} \right) dx du \right]_{u_1} - \frac{\partial \bar{F}}{\partial n} u_1 \\ - \frac{du_1}{dn} \left[\int_0^\infty (-\bar{F} + \Delta F_x + \bar{F}_x) \left(\frac{n_{x1} - n}{u_1} \right) dx \right]_{u = u_1} \end{aligned} \quad (5)$$

By the condition of equilibrium $-\bar{F} + \Delta F_x + \bar{F}_x$ vanishes when u is equal to u_1 , so the coefficient of du_1/dn vanishes; also we know by Gibbs's ad-

sorption equation that $\frac{d\gamma}{dn} = -u_1 \frac{\partial \bar{F}}{\partial n}$. Using this relation, and putting the

differentiation under the integral sign, we have

$$\frac{d\gamma'}{dn} = - \int_0^{u_1} \int_0^\infty \frac{\partial}{\partial n} \left\{ (F_x + \Delta F_x) \left(\frac{n_{x1} - n}{u_1} \right) \right\} dx du \quad (6)$$

We may now investigate the form this takes if we may assume solutions to be perfect. In this case $n_{x1} = ne^{-\frac{\Delta F_x}{RT}}$ and as $u_1 = n \int_0^\infty (e^{-\frac{\Delta F_x}{RT}} - 1) dx$ it is

seen that $(n_{x1} - n)/u_1$ is independent of n . Also $\left(\frac{\partial \bar{F}_x}{\partial n} \right) = \frac{\partial \bar{F}_x}{\partial n_x} \left(\frac{\partial n_x}{\partial n} \right)$ while

$\frac{\partial \bar{F}_x}{\partial n_x} = \frac{RT}{n_x}$ where R is the gas constant and T the temperature and $\left(\frac{dn_x}{dn} \right) = 1$

because $\frac{n_x - n}{u} = \frac{n_{x1} - n}{u_1}$ is a constant. Also it is always true that

$(\partial \Delta F_x / \partial n)$ is zero, for ΔF_x depends only on x . So

$$\begin{aligned} \frac{d\gamma'}{dn} &= - \int_0^{u_1} \int_0^\infty \frac{RT}{n_x} \frac{n_{x1} - n}{u_1} dx du \\ &= - \int_0^\infty \int_0^{u_1} \frac{RT}{n_x} \frac{n_{x1} - n}{u_1} du dx \end{aligned}$$

$\frac{n_{x1} - n}{u_1}$ and n are independent of u in the integration, so expressing n_x in

terms of $\frac{n_{x1} - n}{u_1}$, n and u , by means of the equation $\frac{n_x - n}{u} = \frac{n_{x1} - n}{u_1}$

and performing the integration with respect to u , we get

$$\frac{d\gamma'}{dn} = -RT \int_0^\infty \log \frac{n_{x1}}{n} dx \left(= - \int_0^\infty \Delta F_x dx \right) \quad (7)$$

As in the case of perfect solutions $\frac{d\gamma}{dn} = -\frac{RTu_1}{n} = -\frac{RT \int_0^\infty (n_{x1} - n) dx}{n}$,

we have for purposes of comparison,

$$\frac{d\gamma'/dn}{d\gamma/dn} = \frac{\int_0^\infty \log n_{x1}/n dx}{\int_0^\infty (n_{x1}/n - 1) dx}$$

Now let us call $n_{x1}/n - 1$, which is a quantity which expresses the proportion of the adsorption which takes place at a particular place x , z . We may then write

$$\frac{d\gamma'/dn}{d\gamma/dn} = \frac{\int_0^\infty \log (z+1) dx}{\int_0^\infty z dx} \quad (8)$$

Now if the adsorption is positive z is always greater than zero and $\log (z+1)$ is always less than z . The larger z is the smaller the ratio $\frac{\log (z+1)}{z}$

and the smaller z the nearer the ratio is to 1. Now suppose the chief contribution to u_1 is in some very narrow region so that z is very large in this region, then, of course $d\gamma'/dn$ is absolutely very much smaller than $d\gamma/dn$ (which means, as they are both negative, that γ' is larger than γ). In other words the more the adsorption is confined to a narrow region, i.e., the nearer the adsorbed substance comes to forming a monomolecular layer, the less the dynamic surface tension of the solution should differ from that of the pure solvent. Let us make a calculation assuming z to be constant over a distance of molecular dimensions, say 10^{-8} cm., and zero elsewhere, assuming that $d\gamma/dn = -10$ dynes per mole per liter, and that T is 300° absolute. This makes $\int_0^\infty z dx = \frac{d\gamma}{dn} / RT = 4 \times 10^{-7}$ in C. G. S. units (changing liters to cc.) Since $\int_0^\infty z dx = z \times 10^{-8}$ by the assumptions we have made we find that z is about 40 and $\frac{d\gamma'}{dn} = \frac{d\gamma}{dn} \frac{\log 40}{40} = .08 \frac{d\gamma}{dn}$.

If the adsorption is negative and z is always less than zero, $\log (z+1)$ is always greater than z , absolutely. It will be seen that z does not become less than -1 , and if z is -1 , $\log (z+1)$ is infinite. In this case the change of surface tension with the concentration of the solute is positive, so if the region of adsorption is narrow it means a high value of the dynamic surface tension for a given amount of adsorption, and there is no theoretical limit to the value it might reach.

The Surface Tension of Sodium Oleate Solutions

Recently du Noüy¹ has determined the surface tension of very dilute sodium oleate solutions, using a ring tensimeter. He found that the surface tension of very dilute solutions was very close to that of water, except in the neighborhood of three very sharply defined minima. He also showed, by an apparently unassailable argument, that practically all the sodium oleate was

¹ Du Noüy: Phil. Mag., (6) 48, 664 (1924).

on the surface of the solution and that these three minima corresponded to points where the molecules completely covered the surface in a monomolecular layer, each minimum corresponding to a definite orientation of the molecules of the surface. Du Noüy considers that his method gives a static surface tension. He found, as in his earlier experiments, that the initial value of the surface tension for these dilute solutions was always about that of water, and that it was only after long standing that the final value was reached.

If we attempt to calculate the dynamic surface tension of such solutions we meet with the obvious difficulty that the perfect solution laws cannot hold clear up to the surface. But we would surely expect that it would be somewhat near that of water. One thing is certainly true, $d\gamma/dn$ is very much greater in absolute magnitude than the 10 dynes per cm. per mole used in the example, and this factor would have the effect of making z very much larger and hence $\frac{d\gamma'}{dn} / \frac{d\gamma}{dn}$ smaller than the values we have calculated.

Rayleigh, in the experiments we have already mentioned, also found the dynamic surface tension of sodium oleate solutions to be nearer the surface tension of water than the static. In some cases Rayleigh actually found a greater value for the dynamic surface tensions of these solutions than that of the static surface tension of water. Whether this is a spurious effect, or whether it could be explained if all the factors could be taken into account, is something we cannot at present judge.

We may perhaps be pardoned if we insert at this point a slight digression concerning the interpretation of du Noüy's results. We will grant, what seems extremely probable, that practically (but, of course, not quite) all of the sodium oleate is at the surface of the solution. However this may be, *very* dilute solutions must be perfect even at the surface, and we have Gibbs's equation holding in the form¹ $\gamma_0 - \gamma = RTu_1$ (where γ_0 is the surface tension of pure water. This will not hold for any appreciable concentration, but we can always write Gibbs's equation in the form $d\gamma = -RTu_1 d\log n$ as the perfect solution laws will surely hold far from the surface, it only being near the surface that the concentration is high. n , it must be remembered is the concentration in the interior of the solution, and has no direct connection with the amount which has been added. To better see what happens as sodium oleate is added, we may write $\log n = f(u_1)$ or $d\log n = f'(u_1)du_1$, u_1 being a convenient quantity to take as independent variable because it is approximately proportional to the amount that has been added. In order to account for the large regions in du Noüy's curve in which the surface tension does not vary we must suppose that n or $f(u_1)$ remains nearly constant (and it will be very small) over wide ranges of the value of u_1 . We must also suppose that as u_1 is continually increased that n finally increases, reaching a maximum when the surface tension is a minimum (if we neglect the effect of the variation of u_1 itself in Gibbs's equation), then, as u_1 becomes still larger,

¹ See Herzfeld: Z. physik. Chem., 107, 79 (1921).

actually *decreases*, and that this occurs at each minimum of du Noüy's curve. The maximum value of n would correspond to a completely covered surface with all the molecules in a definite state of orientation. Then, as we crowd more molecules into the surface by changing their orientation we must suppose that their escaping tendency from the surface grows less.

In order to escape this inherently improbable situation, the only alternative that I can see is to suppose that the ring tensimeter, depending as it does on the force necessary to rupture a film, does not give the static surface tension as we have implicitly assumed, but that the "degree of staticness," if we may be allowed the use of such an expression, is determined by the state of the film at the surface, being greatest when the surface is as completely as possible filled with molecules in a certain definite state of orientation, a practically entirely dynamic surface tension being obtained except in the immediate neighborhood of such points.

Summary

The theory of dynamic surface tension is developed from a new point of view, a proof being given on simple thermodynamic grounds that the dynamic surface tension when the surface is extended is greater than the static and when the surface is contracted is less. The above is discussed in connection with other possible points of view. A recapitulation of some of the data in the literature bearing on the subject is given.

It is possible that equilibrium might be established between all parts of the solvent, but not established between the portions of the solute which are respectively near the surface and far from it. A discussion of this possibility is given, considering only the dynamic surface tension of extension, and it is shown that the narrower the region to which adsorption is confined (in the normal situation after equilibrium is established) the larger will be the value of the dynamic surface tension. If perfect solution laws hold clear to the surface the dynamic surface tension can never be greater than the (static) surface tension of the pure solvent if the adsorption is positive, but in case the adsorption is negative an infinite value of the dynamic surface tension is theoretically possible.

Du Noüy's determination of the surface tension of sodium oleate solutions is discussed and his results explained (in apparently the only possible way) on the assumption that his method of the ring tensimeter does not give true static values of the surface tension, but that the "degree of staticness" is determined by the state of the molecules at the surface.

THE GASEOUS REACTION BETWEEN HYDROGEN SULPHIDE AND SULPHUR DIOXIDE

BY H. AUSTIN TAYLOR AND W. ANDREW WESLEY¹

The most important problem which confronts the physical chemist today is the determination of the mechanism of chemical reaction. The interaction of solids is relatively unimportant and the behavior of substances in solution seems in most cases to be highly complex. Therefore great interest attaches to the study of gaseous reactions and the elucidation of their mechanisms.

The rapidity with which hydrogen sulphide and sulphur dioxide react in aqueous solution and the fact that even the most reactive substances become inert upon complete desiccation² suggested that reaction may proceed at a much slower rate, if at all, between the dry gases. Although it has been known for at least a century that hydrogen sulphide does react with sulphur dioxide according to the equation:

nothing definite was known of the manner in which these gases combine in the absence of a liquid phase except that the end products are sulphur and water. The work herein discussed is a study of the kinetics of the reaction, data of which are most valuable in deciding the mechanism of the reaction. The results indicate clearly that the gases are brought into an active condition by adsorption on the walls of the reaction tube, and combine to a very small extent, if at all, in the gaseous phase.

The demonstration of the rapid reaction between hydrogen sulphide and sulphur dioxide in the presence of excess moisture was a common lecture experiment as early as 1812, but it is not known by whom this reaction was first observed. However, Cluzel³ noted at that time that no combination would result if the gases were first dried by passing over calcium chloride. Many investigators⁴ have studied the reaction in a more or less qualitative way, but their results throw little light on the gaseous reaction because they permitted water to condense in the reaction system.

The equilibrium in the reaction has been recently studied in California. Lewis and Randall⁵ were unable to use the method of determining equilibrium by rapidly cooling the reacting substances and analyzing, because the reaction occurs "rapidly in either direction according to the conditions imposed."

They were obliged to use a static manometric method with an excess of liquid sulphur present and were able to work only at one temperature, namely 445°C. Since the change in pressure occurring at this temperature is very small the results, which show an average deviation from the mean of 26 per cent may be regarded as quite satisfactory. Randall and Bichowsky¹ investigated the equilibrium in this system at temperatures above 880°C., where appreciable amounts of hydrogen are present at equilibrium. On the first page of their paper a brief footnote makes the following statement: "A mixture of moist SO₂ and H₂S when passed through a clean glass tube at 60°, deposited but little sulphur. However, when the tube was etched, sulphur was deposited rapidly at the same temperature." This is the only indication in the literature of the true nature of the reaction.

Experiment

The kinetics of the reaction were studied by a dynamic method. The work of Lewis, Randall and Bichowsky demonstrated the difficulty of applying static methods to this system. The gases were allowed to flow at a constant rate through a reaction chamber kept at constant temperature. Determinations of the composition of the gases leaving the chamber permitted the calculation of the rate at which reaction was proceeding. The temperature coefficient was determined through a range of temperatures for two reaction chambers, equal in volume, but of widely different surface area. The effect of variation of partial pressures of the reacting gases was then determined at constant temperature.

Hydrogen sulphide of 99.5 per cent purity can be readily prepared from calcium sulphide as recommended by Pollitzer.² Kahlbaum's chemically pure calcium sulphide in lump form was used in an ordinary Kipp generator with a solution of hydrochloric acid. Before connecting the generator to the remainder of the apparatus about four liters of H₂S were drawn off to ensure the removal of all air. The gas then generated was completely absorbable in 20 per cent sodium hydroxide.

The sulphur dioxide was taken from a cylinder of commercial liquid SO₂. Half of the original contents had been withdrawn, thus removing any air present. Each gas was passed over phosphorus pentoxide before entering the reaction chamber.

In order to obtain accurate measure of the rate of flow of a gas by means of a flow-meter a very steady pressure must be maintained. For this purpose a second Kipp generator containing distilled water was connected to the first and used as a gasometer. A three-way stopcock was used at the mouth of the gasometer so that it could be permanently connected with both the generator and the hydrogen sulphide flow-meter. Since the gasometer contained water it also served to remove all traces of hydrogen chloride carried over from the

¹ J. Am. Chem. Soc., **40**, 368 (1918).

² Z. anorg. Chem., **64**, 121 (1909).

generator. The sulphur dioxide gasometer contained concentrated sulphuric acid and was similarly connected with the cylinder of liquid sulphur dioxide and the sulphur dioxide flow meter.

The flow-meters were of the type described by Benton¹ for very small rates of flow. The capillaries were about one centimeter in length, blown in Pyrex. Distilled water was used in the manometers and was of course saturated with the gas passing through the flow-meter.

From its flow-meter each gas was passed through a large Pyrex U-tube containing phosphorus pentoxide. These drying tubes were sealed directly to the remainder of the apparatus which was entirely of Pyrex. From the drying tube each gas was passed through a stopcock lubricated with metaphosphoric acid. The gases were then mixed and passed directly into the reaction tube. A coil of Pyrex tubing of five millimeters bore joined to a test tube furnished the first reaction tube, which had a volume of 56 cc. and an inner surface area of approximately 320 sq. cm. Reaction tube 2 was blown from two test tubes giving a resultant volume of 51 cc. and surface area of 120 sq. cm.

The reaction tube was maintained at constant temperature in an electric furnace whose inside dimensions were 15 cm. in length by 7 cm. in diameter. The top of the furnace was well insulated with an asbestos board 1.5 cm. in thickness through which the glass tubes connected with the reaction tube and also the thermocouple wires were passed. The current through the furnace windings was controlled by a small rheostat. The temperature was measured by a Hoskins pyrometer, the thermocouple being cemented to the furnace cover so that it occupied the same position in the furnace in each experiment.

The success of this method of determining the extent of reaction depends mainly upon the manner of treatment of the gases coming from the reaction tube. In general, rapid cooling is necessary in order to prevent further reaction but with the system under discussion the gases flowing from the reaction tube cannot be cooled to room temperature. The reason for this is one which all previous investigators failed to observe. If but one droplet of water be allowed to condense in the presence of hydrogen sulphide and sulphur dioxide these gases proceed to react very rapidly in the solution thus formed. Their interaction results in the production of sulphur and more water. However, it was found that cooling to 100°C. effectively stopped the reaction, permitted the complete condensation of the sulphur vapor formed in the reaction tube, and prevented the condensation of moisture. A bulb about 5 cc. in volume was blown in the exit tube at the point at which it projected from the furnace covering. Here the condensed sulphur was permitted to collect. A Pyrex tube 8 cm. in length was sealed to the bulb and was ground at the end to fit the mouth of an absorption bulb. The sulphur bulb and its tube were surrounded by a housing of sheet asbestos which enclosed a 100 watt electric light bulb. The temperature of the enclosure was thus regulated between 100° and 110°C. using a rheostat in series with the lamp.

¹ J. Ind. Eng. Chem., 11, 623 (1919).

The absorption tube was designed to obtain complete absorption without bubbling. Any type of bulb permitting even slight fluctuations in pressure caused by bubbling of the gases through the absorbing liquid rendered the manometer readings of the flow-meters uncertain. Two closed cylindrical bulbs of 1 cm. diameter and 6 cc. volume were connected at one end by a short piece of small tubing so that they were parallel and 1 cm. apart. At the other end one bulb carried a short open tube of 2 mm. bore, while the other bulb terminated in a tube ground to fit the exit of the main train of apparatus and bent so that the absorption bulbs assumed a horizontal position when connected to the exit. In this position a large surface of absorbing liquid was exposed to the gases entering the bulb, and since they dissolve rapidly and completely in that solution, no bubbling could take place.

Each flow-meter was calibrated by absorbing, in 30 per cent sodium hydroxide solution, all the gas passing through it during a definite time interval at various readings of the manometer. The time interval was made long enough to give an increase in weight of the absorption bulb of from 0.15 to 0.2 g. A calibration curve for each flow-meter was made by plotting difference in manometer levels against grams of gas per minute. These curves were checked once a week at several different rates of flow.

The reaction tube was cleaned with a chromic acid cleaning solution and washed well with distilled water. After it was placed in the furnace and sealed to the remainder of the apparatus it was dried at 500°C. with a slow stream of dry sulphur dioxide over-night. This procedure was also of the nature of a heat treatment, since comparable reaction velocities could not be obtained with a fresh tube. It was further found necessary to allow the reaction to proceed for eight or nine hours within the tube before its condition became fixed and duplicate results could be obtained.

The next step was to bring the furnace to the desired temperature at which it was maintained by manual operation of the furnace rheostat within $\pm 1^\circ$ throughout the run. The rate of flow of gases was kept constant by frequent manipulation of stop-cocks. After attaching the weighed absorption bulb in order to make a run, the stop-cocks were not touched since it was found that greater accuracy was achieved by averaging the initial and final readings of the flow-meter manometers during the run. For each run there were recorded initial and final values of the following: time, temperature, the two manometer levels in each flow-meter and the weight of the absorption bulb.

In experiments 1 and 2 at all temperatures below 580°C. the rate of reaction showed a gradual change with time for a period of from 2 to 3 hours. Only when a constant rate of formation of sulphur had finally been reached and several runs differed no more than one per cent from the mean, was the experiment at this temperature discontinued.

The results of experiments 1 and 2 show that the reaction takes place almost entirely on the surface of the reaction tube. Therefore experiment 3 was performed at constant temperature with constant total volume of gas entering the reaction tube but with various partial pressures of hydrogen sulphide and sulphur dioxide.

Calculations and Results

The rate at which H_2S and SO_2 entered the reaction tube was obtained from the average manometer readings by reference to the calibration curves where rates were plotted in grams per minute. A portion of the gas mixture reacted to produce sulphur, which condensed out completely in the sulphur bulb, and water which passed on into the absorption bulb. The increase in weight of the latter is therefore equal to the weight of unchanged H_2S and SO_2 plus that of the water formed. The difference between the total weight of H_2S plus SO_2 which entered the reaction chamber during a run and the increase in weight of the absorption bulb represents the amount of sulphur formed. If this difference be divided by the duration of the run the rate of formation of sulphur is obtained in grams per minute.

It was found in experiment 3 that the rate of the reaction as represented by the rate of formation of sulphur depends upon the partial pressures of the reactants according to the following equation:

$$K = \frac{S}{P_{\text{H}_2\text{S}}^{1.5} P_{\text{SO}_2}}$$

where K is the velocity constant, S is the number of grams of sulphur formed per minute, $P_{\text{H}_2\text{S}}$ is the average partial pressure of the hydrogen sulphide and P_{SO_2} that of the sulphur dioxide.

In order to calculate the average partial pressure of each reactant it is necessary to determine both the initial partial pressures and those after reaction has taken place to the extent necessary to form S grams of sulphur per minute. The latter calculation is complicated by the dissociation of the molecules of sulphur vapor into S_8 , S_6 , and S_2 molecules. The excellent work of Preuner and Schupp¹ on the dissociation of sulphur vapor furnishes the data necessary to compute the average molecular weight of sulphur vapor at various temperatures and at partial pressures between 0 and 180 mm. The latter limit is high enough to include the range of partial pressures produced under the conditions of the experiments being described. These average values were plotted against the corresponding temperatures. This afforded a means of interpolation to intermediate temperatures. Fortunately the error involved in estimating the vapor density of sulphur decreases as the temperature is increased and it is at the higher temperatures only that the volume of sulphur produced becomes large.

The partial pressures of the constituents of a mixture of gases vary but little with change in temperature. It was convenient therefore, to reduce all calculations of partial pressure to normal temperature and pressure, taking care however, to use the value for the molecular weight of sulphur vapor corresponding to the temperature of the experiment.

The data obtained in experiment 2 at 621°C. are the basis of the following computations:

¹ Z. physik. Chem., 68, 129 (1910).

Experimental Data

Temp.	Time	Wt. H ₂ S/min.	Wt. SO ₂ /min.	Wt. absorbed
621°C.	10 min.	0.01105 g.	0.01049 g.	0.1317 g.

Computations

Total Wt. reactants = $0.02154 \times 10 = 0.2154$ g.

Total Wt. sulphur = $0.2154 - 0.1317 = 0.0837$ g.

Wt. sulphur per min. = S = 0.00837 g.

Hereafter all volumes are per minute.

$$\text{Vol. H}_2\text{S} = \frac{\text{Wt. H}_2\text{S per min.} \times 1000}{\text{Wt. Liter H}_2\text{S}} = \frac{0.01105 \times 1000}{1.5392} = 7.179 \text{ cc.}$$

$$\text{Vol. SO}_2 = \frac{\text{Wt. SO}_2 \text{ per min.} \times 1000}{\text{Wt. Liter SO}_2} = \frac{0.01049 \times 1000}{2.9267} = 3.584 \text{ cc.}$$

Total Vol. reactants = 10.763 cc.

Initial $P_{\text{H}_2\text{S}} = 0.667$ atmos.

Initial $P_{\text{SO}_2} = 1 - P_{\text{H}_2\text{S}} = 0.333$ atmos.

$$\begin{aligned} \text{Vol. H}_2\text{S reacted} &= S \times \frac{2 \text{ Mol. Wt. H}_2\text{S}}{3 \text{ At. Wt. S}} \times \frac{1000}{\text{Wt. Liter H}_2\text{S}} \\ &= 3.854 \text{ cc.} \end{aligned}$$

Therefore Final Vol. H₂S = $7.179 - 3.854 = 3.325$ cc.

Similarly Final Vol. SO₂ = 1.679 cc.

$$\text{Vol. S formed} = \frac{S \times 22400}{\text{Mo. Wt. S at } 621^\circ} = 2.678 \text{ cc.}$$

Vol. H₂O formed = 3.899 cc.

Final Total Vol. = Final Vol. H₂S + SO₂ + S + H₂O
= 11.581 cc.

Hence Final $P_{\text{H}_2\text{S}} = 0.287$ atmos.

Final $P_{\text{SO}_2} = 0.145$ atmos.

$$\text{Average } P_{\text{H}_2\text{S}} = \frac{\text{Initial} + \text{Final}}{2} = 0.477 \text{ atmos.}$$

Average $P_{\text{SO}_2} = 0.239$ atmos.

$$P_{\text{H}_2\text{S}}^{1.5} = (0.477)^{1.5} = 0.330$$

$$\text{Hence } K = \frac{S}{P_{\text{H}_2\text{S}}^{1.5} \times P_{\text{SO}_2}} = 0.1061$$

Results

G = Increase in weight of absorption bulb.

S = Number of grams of sulphur formed per minute.

$P_{\text{H}_2\text{S}}$ = Average partial pressure of H₂S

P_{SO_2} = Average partial pressure of SO₂

K = Velocity Constant = $S / (P_{\text{H}_2\text{S}}^{1.5} \times P_{\text{SO}_2})$

T = Absolute Temperature

EXPERIMENT 1

Errors.

Lewis and Randall¹ determined the equilibrium constant at 445°C. for the reaction

at constant partial pressure of sulphur to be

$$K_P = \frac{P_{H_2O}^2 P_{S_2}^{0.5}}{P_{H_2S}^2 P_{SO_2}} = 649$$

The variation of K_P with temperature depends upon Q in accordance with the van't Hoff isochore

$$\frac{d \ln K_P}{dT} = \frac{-Q}{RT^2}$$

To prove that the above K_P is less than that at all temperatures below 445° it is only necessary to show that Q is positive. The following heats of formation are given by Lewis:

¹ Lewis and Randall: "Thermodynamics" (1923).

$3S(l)$ from $3S(\text{rhombic}) = -1401$ calories

$2H_2O(g)$ from $O_2(g)$ and $2H_2(g) = 105640$ calories

$2H_2S$ from $S(\text{rhombic})$ and $2H_2(g) = 9520$ calories

SO_2 from $S(\text{rhombic})$ and $O_2(g) = 69000$ calories

The value of Q is therefore $105640 - 1401 - 9520 - 69000$, that is, 25719 calories. Below 445° the amount of S_2 in the vapor phase is negligible and the exponent of P_S varies from about $\frac{1}{2}$ to about $\frac{3}{8}$.

Not only does the value of K_P increase as the temperature is lowered, but the saturation value of P_S rapidly diminishes. These facts indicate that the product $P_{H_2S}^2 P_{SO_2}$ at equilibrium must diminish very rapidly with decrease in temperature. Since each of the partial pressure values in the equilibrium equation is less than one atmosphere, the product $P_{H_2O}^2 P_S^n$ is always much less than one. Therefore the product $P_{H_2S}^2 P_{SO_2}$ must always be much less than $1/K_P = 0.00154$. Under the conditions of the experiment the value of $P_{H_2S}^2 P_{SO_2}$ in the exit gases was in no case less than 0.003 .

This result proves that it is impossible for the sulphur condensing at the exit of the reaction chamber to react with the water vapor in the exit gases.

The sulphur bulb was maintained at a temperature of between 100° and $110^\circ C$. The vapor pressure of sulphur at $110^\circ C$. is 0.0136 mm.¹ The molecular weight of sulphur vapor at $110^\circ C$. is 256 . The weight of 1 cc. is therefore 0.00083 g. The most rapid rate at which the gases entered the absorption bulb was 14.7 cc. per minute. The weight of sulphur carried into the absorption bulb per minute was therefore $0.0136/760 \times 14.7 \times 0.00083 = 0.000002$ g. The total weight per run of ten minutes duration was 0.00002 g.

The solubility of hydrogen sulphide in liquid sulphur reported by Pélabon² introduced no appreciable error. The amount dissolved increases with rise in temperature and even at $440^\circ C$. is but 0.3 cc. = 0.00045 g. per gram of sulphur. At most only 0.1 g. of sulphur was formed during a run.

The fact that the reaction took place mainly on the surface of the reaction tube eliminates the possibility of the introduction of error due to reaction during the cooling of the gases from the temperature of the reaction tube to that of the sulphur bulb. The amount of surface in the exit tube whose temperature lay between that of the reaction tube and 110° was certainly less than 6 sq. cm. With reaction tube 1 whose surface was about 317 sq. cm. no measurable reaction took place at $180^\circ C$. It was also found that the condensation of sulphur in the sulphur bulb had no measurable effect upon the reaction velocity.

There seem, therefore, to be no inherent errors, so that the accuracy of the results depends upon the errors made in measurement and calculation. A consideration of the errors in the measurement of time, temperature, weight of gas absorbed and rate of flow of reactants showed that the precision was such as would lead to an average deviation of 2.5 per cent in the value of K , the velocity constant.

² Compt. rend., **124**, 35 (1897).

Discussion of Results

1. The Heterogeneity of the Reaction.

The results of experiments 1 and 2 are given graphically in Fig. 1. The values of $\log_{10} K$ are plotted as abscissae against the corresponding values of $1/T$ as ordinates. At 435°C ., where $1/T = 14.12 \times 10^{-4}$, $\log K$ for the reaction tube 1 is -1.315 and for tube 2 is -1.850 . Therefore the reaction proceeded 3.4 times as fast in tube 1 as in tube 2. At 571° this ratio becomes 1.9. In the mean the reaction occurred 2.7 times as fast in tube 1 as in tube 2. The ratio of their surface areas was 317 to 121 or 2.6. This proportionality

FIG. 1

of reaction velocity to surface is definite evidence that there can be little reaction between H_2S and SO_2 in the gas phase. The volumes of the two tubes were almost equal at 56 and 51 cc. respectively.

2. The Temperature Coefficient.

The variation of the velocity constant of a chemical reaction with temperature may be expressed by the Arrhenius equation: $d \ln K/dT = E/RT^2$ or in the integrated form:

$$\log K_2/K_1 = E/4.57(1/T_1 - 1/T_2)$$

When T_1 and T_2 are temperatures 10° apart, the value of K_2/K_1 is called the temperature coefficient of the reaction velocity. The values so calculated are given in the following table:

Temp. °C	Experiment 1		Experiment 2	
	Temp. Coef.	E Cal./Mol.	Temp. Coef.	E Cal./Mol.
370	1.239	17600	—	—
400	1.169	14000	—	—
435	1.151	14000	1.170	15600
475	1.134	14000	1.151	15600
510	1.076	8900	1.137	15600
550	1.037	4900	1.093	11900
600	—	—	1.058	8500
680	—	—	1.045	8000

The values of E thus calculated are probably not equal to the actual heats of activation of the chemical reaction involved. The amounts of reacting substances adsorbed on the surface of the vessel and therefore actually participating in the reaction, undoubtedly decrease with a rise in temperature. This would make the apparent value of E, calculated from the observed temperature coefficient, smaller than the true value which measures the actual stability of the adsorbed molecule.

It can be seen that the temperature coefficient decreases with increase in temperature. At lower temperatures it is comparatively high, then decreases steadily. This variation is in accord with the theory that the reaction velocity depends upon the amount of reactants adsorbed, the resultant temperature coefficient being equal to the sum of the negative temperature coefficient of adsorption and the positive coefficient of the chemical reaction. There are no data available which show the heats of adsorption of SO₂ and H₂S on glass at high temperatures. The magnitude of the effect of temperature on the adsorption of these gases cannot be estimated, so that the true heat of activation for the reaction between H₂S and SO₂ on glass surfaces cannot yet be calculated.

The fact that the temperature coefficients of the reaction were different at a given temperature for the two reaction vessels used is probably due to a slight difference in the surfaces. It may be that only the SiO₂ groups of the surface are active in adsorption of H₂S or SO₂, or that only the Na₂O groups can activate these gases. Again it may be that each of these groups activates one of the reactants. Further study of the adsorptions may determine the exact details of the mechanism at the surface. It is remarkable indeed, in view of the recent work of Hinshelwood on the decomposition of formic acid¹, that the curves of log K against 1/T are so nearly parallel. Hinshelwood found that the velocity of the decomposition of formic acid and the relative ease with which it follows the two alternative paths of reaction to form H₂ + CO₂ or H₂O + CO are very sensitive to the nature of the glass surface. At 300°C. for example, the amounts of CO₂ + H₂ in the products of formic acid decomposition on equal surface areas were:

¹ Proc. Roy. Soc., 100 A, 575 (1922); J. Chem. Soc., 121, 1668 (1922); 123, 1014, 1333 (1923).

Duro glass	74%	73%	63%
Soda glass	19.1%	18.3%	16.5%

Duro glass is similar in composition to pyrex glass.

3. *Mechanism of the Reaction.*

Examination of the results tabulated for experiment 3 shows immediately that the rate of formation of sulphur is directly proportional to some power of the partial pressure of each of the reactant gases. This suggests that both gases are adsorbed and only adsorbed molecules react. If but one of the gases is adsorbed and reaction takes place when a molecule of the other gas collides with an adsorbed molecule, there is a range of pressures through which the reaction velocity is independent of the partial pressure of the adsorbed type of gas. In this range the surface of the catalyst is saturated with adsorbed gas and the velocity depends upon the number of molecules of the unadsorbed type which strike the surface. At constant temperature, the rate at which the molecules of a given gas strike a plane surface is directly proportional to the pressure of the gas. Langmuir¹ found that at high temperatures the surface of platinum in a mixture of carbon monoxide and oxygen is nearly covered with oxygen, and the velocity is then limited by the rate at which the monoxide strikes the surface.

If both the gases are adsorbed and only one is activated by the adsorption, the reaction velocity will be directly proportional to the fraction of surface covered by the activated gas, and inversely proportional to the fraction of surface covered by the inert gas. The results obtained by Bodenstein and Ohlmer² on the oxidation of carbon monoxide on quartz, in which case the adsorbed carbon monoxide is inert, and the results of Bodenstein and Fink³ on the oxidation of sulphur dioxide, in which case the adsorbed SO₂ is inert, indicate just such a mechanism.

The results of experiment 3 are best explained by assuming that both the H₂S and SO₂ are adsorbed and that reaction takes place only between these adsorbed molecules. If this is indeed the case, then the reaction velocity would be proportional to the fraction of surface covered by groups consisting of one SO₂ and two H₂S molecules situated adjacently. The probability of this condition occurring is proportional to the product of the square of the fraction of surface covered by H₂S times the fraction of surface covered by SO₂. Let F_{H₂S} equal the fraction of surface covered by H₂S and F_{SO₂} the fraction covered by SO₂ molecules. Then the velocity will be given by:

$$S = k F_{\text{H}_2\text{S}}^2 F_{\text{SO}_2}$$

The fraction of surface covered by an adsorbed gas is given by the Freundlich isotherm:

$$F = a P^{1/n}$$

¹ Trans. Faraday Soc., 17, 621 (1921).

² Z. physik. Chem., 53, 175 (1905).

³ Z. physik. Chem., 60, 1 (1907).

Therefore,

$$F_{\text{H}_2\text{S}} = k_1 P_{\text{H}_2\text{S}}^{1/n}$$

$$F_{\text{SO}_2} = k_2 P_{\text{SO}_2}^{1/m}$$

Substituting,

$$S = K P_{\text{H}_2\text{S}}^{2/n} P_{\text{SO}_2}^{1/m}$$

The adsorption of H_2S on glass surfaces has not yet been studied. Therefore the value of $1/n$ is not known. Bangham and Burt¹ have studied the adsorption of SO_2 on glass quite recently but their research "brought to light a conspicuous difference in the behavior of SO_2 from that of any gas previously tested" (N_2O , NH_3 and CO_2). Continued heating in vacuo at 200°C . did not remove all the adsorbed SO_2 so that they were unable to evaluate the pressure exponent. However, McGavack and Patrick² found that for SO_2 adsorbed by silica gel the value of $1/m$ is 0.485 at 30°C ., 0.533 at 57° , 0.662 at 80° and 0.745 at 100°C . If these values be extrapolated it will be seen that the value of $1/m$ approaches 1 asymptotically at about 150°C . It seems reasonable therefore, to conclude that the value in the above expression at temperatures above 350°C . is nearly 1.

The value of $2/n$ must lie somewhere between 2 and 0. Various exponents for $P_{\text{H}_2\text{S}}$ lying in this range were used in calculating velocity constants and the results are tabulated in experiment 3, Table II. It will be seen that the smallest average deviation is obtained where $2/n = 1.5$. This indicates that the pressure exponent for hydrogen sulphide at 480°C . is about 0.75. At high temperatures the pressure exponents of adsorption vary but slowly with temperature.

Very few data have yet been determined on reactions at catalyst surfaces where both reactants are adsorbed and activated. None are available for any reaction of the same type as the one studied, where the reaction is apparently trimolecular and both gases activated by adsorption. Pease³ found that the velocity of combination of ethylene and hydrogen at copper surfaces could be expressed by an equation

$$K = \frac{dP/dt}{V_{\text{H}_2}^{0.80} V_{\text{C}_2\text{H}_4}^{0.66}}$$

where dP/dt = rate of decrease of pressure

V_{H_2} = initial volume of hydrogen

$V_{\text{C}_2\text{H}_4}$ = initial volume of ethylene.

The mechanism of this reaction is quite similar to the $\text{H}_2\text{S}-\text{SO}_2$ reaction but it is bimolecular and hence simpler.

Summary

1. Measurements have been made of the velocity of combination of hydrogen sulphide and sulphur dioxide in Pyrex reaction tubes at temperatures ranging from 370 to 730°C . The velocity was found to be proportional to the surface area of the reaction chamber, which proves that the glass surface

¹ J. Phys. Chem., **29**, 548 (1925).

² J. Am. Chem. Soc., **42**, 946 (1920).

³ J. Am. Chem. Soc., **45**, 2235 (1923).

acts as a contact catalyst for the reaction. Further the temperature coefficient was found to decrease with a rise in temperature.

2. Measurements of the velocity at constant temperature show it to vary directly as the partial pressure of the sulphur dioxide and as the partial pressure of the hydrogen sulphide raised to the 1.5 power.

3. A mechanism of reaction in harmony with the modern theories of heterogeneous reactions has been suggested, and substantiated by the results. According to this mechanism each of the reactants is activated by adsorption on the surface of the glass and reaction then follows between the activated molecules only.

New York, N. Y.

AN IMPROVED DYNAMIC METHOD FOR MEASURING VAPOR PRESSURES

J. N. PEARCE AND R. D. SNOW

In the study of the colligative properties of solutions use may be made of methods involving the lowering of the freezing point, the lowering of the vapor pressure and the elevation of the boiling point of the solvent by the solute, and the application of electromotive force methods. Because of the ease and the accuracy of the measurements most of the work, hitherto, has been confined to the application of the freezing point and electromotive force methods. Both the freezing point and the boiling point methods are of limited application because of the fact that they can be used accurately only for a narrow temperature interval. The latter method is further handicapped for the reason that we have no accurate specific heat data for liquids at temperatures near their boiling points. While the electromotive force methods may be used at any temperature, they are limited to only those cases for which perfectly reversible electrodes are obtainable.

Of all the properties of solutions none are more accessible to thermodynamic treatment than the vapor pressure. While the method is free from all of the disadvantages of the above mentioned methods and in addition offers many advantages, the results obtained have not been all that could be desired.

Four general methods have been employed for measuring the vapor pressures of solvents and solutions. They are: (1) static, (2) indirect, (3) differential, and (4) dynamic.

The static method has been used by many investigators, including Wüllner¹ and Raoult². In principle, this method consists essentially in placing the liquid whose vapor pressure is to be determined above the mercury in a Torricellian vacuum and comparing the height of the mercury with that in another barometer tube at the same temperature. Tammann³ has shown, however, that the method is open to serious errors due to small traces of air and volatile impurities unavoidably present in the solution and on the sides of the tubes. Furthermore, there is no assurance that the concentration of the solution remains uniform throughout.

The indirect method, as perfected by Ramsay and Young⁴, consists in observing the temperatures at which solutions boil under various pressures. They have used the method extensively and their results on the vapor pressure of water above 100° are still accepted as standard. Emden⁵, and Holborn

¹ Wüllner: *Pogg. Ann.*, **103**, 529 (1856); **110**, 564 (1860).

² Raoult: *Z. physik. Chem.*, **2**, 353 (1888).

³ Tammann: *Wied. Ann.*, **33**, 322 (1888).

⁴ Ramsay and Young: *Phil. Trans.*, **103A**, 107 (1892).

⁵ Emden: *Wied. Ann.*, **31**, 145 (1897).

and Henning¹ have used the method to measure the vapor pressures of many aqueous solutions. The objections to the indirect method are: (1) the liquid and the vapor are both liable to become superheated; (2) in the case of solutions, the concentration is changed by the evaporation of the solvent, and (3) the method is limited by the fact that many solutes decompose on boiling.

The differential method involves the comparison of the vapor pressures of two solutions, or of one solution and the pure solvent, by means of a manometer or a flexible membrane, and it gives directly the vapor pressure lowering. It does not, however, give us any knowledge of the absolute value of the vapor pressure over either liquid phase. Dieterici² separated the vapor above two different liquids by a flexible metallic membrane and measured the difference in vapor pressure by the movement of this membrane as magnified by a long pointer. The apparatus is too complicated and inflexible for general application. Fraser and Lovelace³ have developed a modification of the differential method by which the vapor pressure lowerings may be determined with extreme accuracy. They compare the vapor pressure of a solution with that of the pure solvent by means of a very sensitive Rayleigh manometer. With this apparatus they have been able to measure the vapor pressure lowerings in solutions of potassium chloride, mannite and lithium chloride at 20° with an accuracy of 0.001 mm., or less. The apparatus and its technique require extreme precaution in the preparation of air-free solutions and in keeping them in constant agitation. The time consumed, which varies from several days to several weeks for a single determination of the vapor pressure lowering, makes the method impractical for any but the most refined work. Tower and Germann⁴ have measured vapor pressure lowerings in aqueous and alcoholic solutions by means of a Morley gauge.

The dynamic, or air-saturation method of measuring vapor pressures, is based upon Dalton's Law of partial pressures. The essential features of the method as commonly used are: (1) a measured volume of air is saturated with vapor by passing it over the surface of, or bubbling it through the liquid contained in the saturator, (2) the weight of the solvent evaporated is determined by the loss in weight of the saturator, or by the gain in weight of an absorber which removes the solvent from the effluent air, and (3) the total pressure exerted by the gaseous mixture in contact with the liquid is obtained from barometer and manometer readings. From the data thus obtained the vapor pressure of the liquid may be calculated.

Regnault⁵, the first to use the dynamic method, passed air through a flask containing a sponge saturated with the liquid, then through screens of moist silk fastened to frames. The water vapor in the effluent air was determined by absorption in sulphuric acid and subsequent weighing. Since

¹ Holborn and Henning: *Ann. Physik*, (4) 26, 833 (1908).

² Dieterici: *Wied. Ann.*, 50, 47 (1893); *Ann. Physik*, (4) 70, 617 (1923).

³ Fraser, Lovelace, and students: *J. Am. Chem. Soc.*, 38, 515 (1916); 42, 1793 (1920); 43, 102 (1921); 45, 2930 (1923).

⁴ Tower and Germann: *J. Am. Chem. Soc.*, 30, 1219 (1908); 36, 2449 (1914).

⁵ Regnault: *Ann. Chim. Phys.*, (3) 15, 129 (1845).

Regnault's time the apparatus employed has undergone many and varied changes. In the modification developed by Ostwald and later used by Walker¹, air is bubbled through two Liebig bulbs containing the solution, then through pure water, and finally through a U-tube containing pumice soaked with sulphuric acid. The air first saturates itself with vapor up to the vapor pressure of the solution and then takes up from the water the quantity of vapor necessary to complete the saturation. Finally, the water is absorbed by sulphuric acid. From the loss in weight of the water bulb, which is proportional to the difference between the vapor pressures of the solution and solvent, and the gain in weight of the acid tube, the relative lowering of the vapor pressure of the solvent is calculated. With slight variations in the apparatus and technique the method has been used with more or less success by a number of investigators.

The Earl of Berkeley and Hartley² have concluded that the failure of the original Walker-Ostwald method is due to variations in the hydrostatic pressure in the several vessels. They also suggest that liquid spray is mechanically carried from the solution to the pure solvent. Both of these sources of error were eliminated by passing the air slowly over the surface of the liquid contained in specially designed tubes shaken by the oscillating platform upon which they were mounted. The time required to make a complete vapor pressure determination was about three days and they claim an accuracy of the order of five percent.

Derby, Daniels and Gutsche³ have determined the vapor pressures of pure alcohol and pure water by passing a measured volume of air axially through two rotating spherical bulbs filled with glass beads and partially filled with the liquid. The volume of air was accurately measured by means of two bulbs, each holding exactly 1135 c.c. The method employed was found to be quite accurate and very rapid. While they usually used from 8 to 10 liters of air for each experiment, they found that as much as 50 liters of air can be passed through the solution in one hour without affecting the efficiency of the saturator or the absorber.

Washburn and Heuse⁴ have measured the relative lowering of the vapor pressure for weight molal solutions of cane sugar. They used saturators similar to those used by Berkeley and Hartley, but passed the air in succession through the following train: The air, drawn by a constant level aspirator, passes first through a soda-lime tube and then into the water presaturator, where it is saturated with water vapor at about 50°. The air then passes into a condensation flask which is immersed in the thermostat and here it deposits most of its excess of moisture and enters the first saturator of the train slightly supersaturated. On emerging from this saturator it is in equilibrium with water at 25°. It then passes out of the thermostat through a tube which is

⁴ Washburn and Heuse: *J. Am. Chem. Soc.*, **37**, 309 (1915).

heated by a coil to about 30° . The warm air then passes at once through an absorber, A_1 , where all of the moisture is removed. The perfectly dry air then goes through a second presaturator containing water at 25° where it takes up the bulk of the moisture necessary to bring it into equilibrium with the solution in the saturator, S_2 . After passing through this saturator and its absorber, A_2 , the perfectly dry air passes directly into the third saturator, S_3 , which contains pure water. In the first and third saturators the equilibrium is always approached from opposite directions, thus giving a valuable check upon the experimental conditions. The absorbers are large; about 25 grams of water can be condensed and absorbed in one absorber. Although the apparatus is very large and apparently cumbersome, it is, nevertheless, capable of a high degree of accuracy. In the use of this apparatus the measurement of the volume of air is unnecessary, since the same volume of air passes in turn over the solution and over the solvent, and the weight of the water evaporated from each is determined by the gain in weight of its respective absorber. A single experiment extends over a period of 24 hours, and they claim that the results are accurate to less than 0.5 percent.

A survey of the vapor pressure data obtained by the dynamic method shows not only a wide variation in the values reported by different investigators for a single liquid, but also very frequently a considerable variation in the data given by a single investigator. The chief reasons for these deviations are few, but they have been difficult to overcome. As mentioned before, one of the main sources of error is due to our inability to measure accurately, and at the same time conveniently, the large volume of air required for a single determination. The error thus introduced will be greater or less depending upon the magnitude of the vapor pressure of the liquid studied. This difficulty has been practically eliminated by the method of Washburn and Heuse but the apparatus is almost too cumbersome from the standpoint of convenience and speed. It is also largely eliminated in the method of Derby, Daniels and Gutsche but their apparatus requires constant and immediate attention. Owing to the surface film effect any form of apparatus which requires the passing of air over the surface of the solvent or solution must present a large liquid surface. Moreover, the surface should be in constant motion. Forms of apparatus involving the bubbling of air through the liquid are obviously more compact, but they introduce errors for the reason that while a bubble may be saturated with the vapor in the depth of the liquid, it will expand on rising and may become unsaturated. Unless, therefore, the air passes over the surface of the liquid again it may leave the apparatus without becoming entirely saturated. Again the mathematical formulae which have been used, heretofore, have been complicated; slight errors of observation are highly magnified in calculating vapor pressures.

In the pages which follow we shall describe an apparatus and its technique which greatly improves the dynamic method and eliminates many if not all of the difficulties experienced in the past

Apparatus

To reduce the errors involved in measuring the large volume of gas passed through the liquid we have generated the gas electrolytically and we are able to calculate indirectly from the mass of silver deposited in the coulometer not only the actual volume of the gas, but also the total number of mols of hydrogen and oxygen. The final form of the apparatus is shown in Fig. 1. Six electrolytic gas cells, A, are connected in series through the silver coulometer,

FIG. 1

S, with the laboratory storage battery system. The gases generated pass through a manifold tube into the presaturator, B, maintained at a few degrees higher than the bath temperature. From B the gases pass to the saturator, C, consisting of a battery of four saturation tubes sealed in series and containing pure conductivity water. In this way the moisture content of the gas is reduced to the normal saturation pressure at the temperature of the experiment. The gas then passes to a bank of four similar absorbers, D, containing the solution under investigation, where the vapor pressure falls to the normal vapor pressure of the solvent over the solution. Both C and D are immersed in a large Freas water thermostat maintained at $25^{\circ} \pm 0.002$. Finally, the saturated gases pass through the absorber, E, and the protection tube, F, to the atmosphere.

Generators

The generators were wide mouth glass bottles of three and one-half liters capacity, each filled to the neck with a 25 percent solution of sodium hydroxide. The electrodes were of nickel wire gauze, each 3.5 by 9 inches, suspended by heavy nickel wire leads. The leads were inclosed by glass tubes passing through the rubber stopper. The tubes were fused to the wire at the bottom for a length of one inch, filled with melted paraffin and then sealed at the top with sealing wax to prevent leaks. The electrodes were separated by a glass cylinder extending through the middle two-thirds of the depth of the solution, thus preventing any possible recombination of the gases due to the catalytic influence of the nickel. The top of each electrolytic cell was hermetically sealed with De Khotinsky cement.

Saturators

The saturators were of the type used by Bichowsky and Storch¹. The gases enter the bulb (Fig. 1. B) through a short central tube tapered down to a 2 mm. capillary. At the tip of the capillary the stream of gas breaks into bubbles which pass up a slightly inclined 5 mm. tube 10 inches long and then break at the end of the tube. An opening is blown through the lower side of this inclined tube just back of the tip of the capillary. Through this opening liquid is drawn from the bottom of the saturator and carried by the gas bubbles up the slanting tube to the surface of the liquid, thereby maintaining a practically uniform vapor concentration. The gas liberated from the bubbles as they burst then passes back over the surface of the liquid to an orifice leading either to a second saturator, or, finally, to the absorber, E. Each tube in a saturator, C or D, is provided with a vertical tube for filling and emptying. When the saturators are in use these tubes are closed by mercury seal stoppers.

This type of saturator has three distinct advantages over the Liebig bulb and the ordinary wash bottle type of saturators. They are: (1) each bulb introduces only a small hydrostatic pressure (about $1/2$ inch of water), (2) after this pressure is released by the breaking of the bubble, the gas passes for some distance over the surface of the liquid, thereby having opportunity to come into equilibrium with the latter, and (3) the liquid is more efficiently stirred.

Absorber

The absorber consists of a six inch glass-stoppered U-tube joined by means of a mercury seal to the last bulb of the saturator D. The absorber contains glass beads which have been thickly coated with phosphorus pentoxide by rotating the beads in a bottle containing the oxide. This type of absorber exposes a large surface to the gases without offering any appreciable resistance to the flow. The protection tube F also contains beads similarly coated; this prevents moisture diffusing into the absorber from the atmosphere.

The silver coulometer used was of the porous cup type. The specifications proposed by Rosa and Vinal² were minutely followed. The electrodes were

¹ Bichowsky and Storch: *J. Am. Chem. Soc.*, **37**, 2696 (1915).

² Rosa and Vinal: *Bull. Bureau of Standards*, **13**, 497 (1917).

supported by heavy glass rods set in iron stands. The anode was cast in the form of a cylinder from pure silver; the cathode was a platinum dish of 250 to 300 c.c. capacity. The porous cup was soaked in dilute nitric acid for several days, then distilled water was filtered through it, and it was finally heated at 130° to remove the last traces of acid. A solution of 15 grams of silver nitrate in 100 c.c. of water was used for the electrolyte.

The temperature of the bath was read from a normal glass thermometer, (B. S. No. 21577); the smaller fluctuations in temperature were indicated by means of a Beckmann thermometer immersed at the same point in the bath. Barometric pressures were read from a large precision barometer, readable by vernier to 0.05 mm. All pressures were reduced to 0°, sea level and 45° latitude.

Materials

Mannite. Pfanstiehl's "C. P." mannite was further purified according to the method of Brahme¹. It was twice precipitated from distilled water and once from conductivity water by the addition of alcohol. After a second recrystallization it melted sharply at 166°. It was then dried and heated to constant weight at 125°-130°.

Potassium Chloride. A good "C. P." sample of the salt was twice recrystallized from pure distilled water and once from conductivity water. After drying, the salt was heated in a platinum dish until decrepitation ceased and then preserved in a desiccator over P₂O₅ until used.

Silver. The silver used as anodes was specially prepared and the analysis showed that it was 99.8 percent pure. It was further purified by electrolysis, then fused and cast in the form of cylinders. Chemically pure silver nitrate was twice recrystallized from dilute nitric acid solution and then repeatedly fused with excess nitric acid to remove organic impurities.

The various molal solutions of potassium chloride and mannite were made with water distilled from an alkaline permanganate solution and condensed in a block tin condenser.

Experimental

In order to avoid the evaporation and condensation of any solvent on the walls of the tube leading from the solution saturator, the current was turned through the coil surrounding the mercury seal. At the same time the direct current was switched through the electrolytic cells and gas was passed through the saturators for about one-half hour before the coulometer or the absorber were attached.

The absorber, E, was counterpoised on a sensitive balance by a similar U-tube filled with glass beads. After coming to equilibrium, one stopper of each tube was temporarily opened and the final weighing was made. A platinum dish cathode, previously cleaned, dried at 150° and cooled in a desiccator, was accurately weighed. All weighings were made by the oscillation method and are accurate to ± 0.01 mg. At the end of the half hour period the switch to the generator was opened, the coulometer assembled,

¹ Brahme: J. Am. Chem. Soc., 41, 1707 (1919).

and the absorber and protection tube were put in place. The current was immediately switched through the whole system and the barometer reading was taken. Barometer readings were taken at frequent intervals throughout the experiment. At the end of the experiment the current was shut off and the absorber and protection tube were connected by another mercury seal to a long glass tube containing beads coated with P_2O_5 . An aspirator was attached to F and dry air was drawn through the absorber to displace the gaseous mixture of hydrogen and oxygen, and to carry any vapor condensed on the side arm of the absorber into the absorber itself. Aspiration was continued for an hour, after which the absorber was removed, closed, wiped with clean dry chamois skin, and then allowed to stand in the tightly closed balance case over night. The final weighings were made with one stopcock open. Repeated aspiration of the absorber with dry air did not measurably change the final weight. At the completion of the experiment the electrolyte was siphoned from the platinum dish and the deposit was washed free from silver nitrate. The dish was then dried for an hour at 150° , cooled in a desiccator and weighed.

From the three data thus obtained, viz., the weight of the water evaporated, W_w , the weight of the silver deposited, W_s , and the corrected barometer pressure, P , the vapor pressure of the solution can be easily calculated by a direct application of Dalton's law. Thus, if the mixture of hydrogen, oxygen and water vapor are in equilibrium with the solution at the atmospheric pressure, P , (corr.), then the partial pressure of the water vapor, p , in the mixture will be proportional to its mol fraction. That is,

$$p = \frac{n_1}{n_1 + n_2} P,$$

where n_1 is the number of mols of water vapor and n_2 is the number of mols of hydrogen and oxygen combined. n_1 is calculated from the weight of water vapor collected in the absorber and the molecular weight of water, thus $n_1 = W_w/18.016$. n_2 is obtained from the weight of silver deposited in the coulometer. While the electrochemical reaction:

is taking place at the coulometer cathode six mols of hydrogen and three mols of oxygen are being liberated in the six generators, or nine mols of gas for every two equivalents of silver deposited. Therefore,

$$n_2 = W_s/2 \times \frac{107.88}{9} = \frac{W_s}{23.9733}.$$

In the final form the expression for vapor pressure reduces to

$$p = \frac{\frac{W_w}{18.016}}{\frac{W_w}{18.016} + \frac{W_s}{23.9733}} \times P.$$

For example, let us assume the data from the first experiment in Table I. Here, $W_s = 16.5944$ g. Ag, $W_w = 0.41325$ g. water, and $P = 740.43$ mm. The value of p , the vapor pressure of water at 25° , is found to be 23.7496 mm.

The simplicity of this method of calculating vapor pressures is apparent. It is only necessary to know three experimental values,—the corrected barometric pressure, and the weight, W_w , of water collected in the absorber while W_s grams of silver are being deposited in the coulometer. This indirect method of measuring the volume of gas passed through the liquid is unquestionably more accurate than any method used heretofore. Furthermore, the simple mol fraction equation, $p = xP$, used in the calculation does away with the complicated equations, and their many uncertain constants, required in other dynamic methods. The only point about which a question may be raised is the assumption of the validity of Dalton's law. In a sense, this method reduces vapor pressures to the same basis as that used in calculating atomic weights, viz., $Ag = 107.88$.

Application of the Method to Aqueous Solutions

As a test of the accuracy and duplication attainable we have applied the method to the measurement of the vapor pressures of pure water and aqueous solutions of potassium chloride and mannite. The results are collected in Tables I-IV. These are self-explanatory.

TABLE I

Mean						23.752

The results thus obtained for water vapor show better agreement among themselves than those generally obtained by dynamic methods, heretofore. In only one case is the deviation from the mean as great as 0.007 mm. Also, the mean value, 23.752 mm., is identically the same as that obtained by Derby, Daniels and Gutsche¹, and it agrees favorably with the other values for the vapor pressure of water found in the literature. The following values have been obtained by other investigators at 25° .

The complete data for the vapor pressures of aqueous solutions of potassium chloride are given in Table II. In this we have included all of the data obtained for each concentration of the salt, and we have simply taken the mean values without rejecting those values which appear to be in error. In some cases the agreement between the values for any one concentration is less than one might desire, and less, also, than the accuracy of which the method is capable. The vapor pressure values for the various solutions, however, are in general more consistent than those obtained by other modifications of the dynamic method. Most of the data presented was obtained during the extreme heat of the summer session. The deviations observed are due almost entirely to difficulties in controlling the temperature conditions accurately over a period of several hours. Under ideal conditions there is no reason why the accuracy obtainable should not approach that of the silver coulometer itself.

The values for the molal lowering of the vapor pressure are given in the last column. While they show considerable irregularity, they show also the same general trend as those calculated by Fraser, Lovelace and Sease⁸, using their very accurate differential method. They have found that the curve for the plot of the molecular lowering of the vapor pressure, $(p_0 - p)/m$, against the molar concentration passes through a distinct minimum at about 1.0 m, with a slight irregular hump in the curve between 0.4 m and 0.8 m. A rough plot of similar data obtained by our apparatus also shows a minimum in the molal lowering of the vapor pressure at 1.0 M, but the hump has its maximum in the neighborhood of 1.5 M. While there is undoubtedly a minimum value, the average value for the molal lowering for the twelve concentrations studied is 0.7572 mm. At no concentration does the deviation from this value exceed ± 0.02 mm., a value which could easily be accounted for by an error of 0.02 mm. to 0.03 mm. in the vapor pressure reading.

To test the efficiency of the apparatus further we have measured the vapor pressures of four aqueous solutions of mannite. The results obtained are given in Table III.

The values for the vapor pressure of the solvent for the two series of solutions are graphically shown in Fig. 2. The extreme smoothness of the curves and the fact that the points fall so nearly upon a straight line speak for the accuracy obtainable by the method. The curve for mannite is a straight line throughout. For potassium chloride solutions up to 3.5 M the maximum displacement from the straight line curve does not exceed 0.02 mm., and at 4.8 M the deviation is only 0.10 mm. The striking apparent proportionality between the vapor pressure lowering, $p_0 - p$, and the molality for solutions of potassium chloride up to 0.6 M is shown in Fig. 3. Within limits of experimental error the curve for mannite solutions is a straight line, as we should expect.

TABLE IV

Observed and Calculated Vapor Pressure Lowering produced by

Mannite at 25°

M	X mol fract.	P mm.	p ₀ - p obs. mm.	p ₀ - p calc. mm.	p ₀ - p M mm.
0.0	0.000000	23.752	0.000	0.000	
0.4	0.007155	23.586	0.166	0.169	0.415
0.6	0.010694	23.499	0.252	0.254	0.420
0.8	0.014208	23.415	0.337	0.3375	0.421
1.0	0.017697	23.328	0.424	0.420	0.420

According to Raoult's law the lowering of the vapor pressure of a solvent is directly proportional to the mol fraction, x , of the solute. For comparison, the observed values for $p_0 - p$ for mannite solutions and those calculated from Raoult's law are given in Table IV. The last column contains the calculated values for the molal lowering of the vapor pressure produced by mannite. In both cases the agreement is satisfactory.

FIG. 2

FIG. 3

Summary

1. A new modification of the dynamic method of measuring vapor pressures has been developed.

2. The method introduces the following new features. Instead of measuring the volume of air which passes through the solution, hydrogen and oxygen are generated electrolytically, and the volume of the mixed gases, as well as the number of mols of each, is calculated from the weight of silver deposited in a coulometer.

3. The actual calculation of the vapor pressure requires the knowledge of three single values, viz., the corrected barometric pressure, P , and the weight of the vapor, W_w , taken up by the absorber while W_s grams of silver are being deposited in the coulometer. The number of mols of water vapor, n_1 , and the total number of mols of hydrogen and oxygen, n_2 are calculated from W_w and W_s , respectively. From this data the vapor pressure of the solvent is calculated by means of the simple equation,

$$p = \frac{n_1}{n_1 + n_2} P.$$

4. The method has been applied to the determination of the vapor pressures of pure water and aqueous solutions of potassium chloride and mannite at 25°*.

The State University of Iowa.*

* The method is being extended to the determination of the vapor pressure of aqueous solutions up to the limits of solubility.

THE METHANE EQUILIBRIUM. III

BY R. C. CANTELO

A. The Catalytic Decomposition of Ethylene

(1) The Materials used:

Ethylene—The ethylene was prepared by the action of phosphoric acid upon absolute alcohol. The gas so prepared analyzed 96-98% C_2H_4 .

(2) Contact Materials:

Of the various contact agents used, nickel reduced from the oxide was the only efficient one. It alone will be considered here. The catalytic nickel was prepared according to the method described in the first paper of this series.

(3) The Apparatus:

This consisted of a "train" similar to that described in the previous paper. The reaction chamber was a Pyrex glass tube which was heated in a specially constructed gas oven. The temperature of the tube was taken by two thermometers placed in contact with the glass tube; and the temperature of the oven could be controlled easily to 5 degrees.

(4) Experimental Method:

In the first series of experiments the gas was passed but once over the catalyst; but in those experiments designed to test the stability of ethane at $360^{\circ}C$, the gaseous products were passed backwards and forwards over the catalyst a varying number of times at the rate of one to two liters per hour. Hydrogen was used for the preliminary washing-out of the apparatus.

The gaseous products were collected in every case over a 1:1 mixture of glycerol and water.

(5) Method of Analysis:

Carbon dioxide, unsaturated hydrocarbons, oxygen and carbon monoxide were determined by the usual absorption methods.

Hydrogen was determined by combustion at $270-300^{\circ}C$ with copper oxide in a small quartz tube, heated in a small gas oven the temperature of which could be controlled easily. To assist the rate of combustion of hydrogen, some metallic copper was always present at the start of the combustion.¹ The reduction in volume after combustion was equivalent to the c.c. of hydrogen in the gas.

It was found, however, that when the percentage of hydrogen in the gas was small, there was some loss due to the combustion of some ethane. This was overcome by adding 15 to 20 c.c. of pure electrolytic hydrogen. Tests then showed the method to be satisfactory. The temperature for rapid and complete combustion of hydrogen alone varied slightly with the quartz tube used. For the tube finally used in this series, the average temperature was $280^{\circ}C$.

¹ Pease and Taylor: J. Am. Chem. Soc., **34**, 2179 (1921).

Methane and ethane were determined in the residue from the combustion of the hydrogen. The quartz tube was heated directly by a free flame some 3 inches wide, and the temperature was that of a bright red heat.

From the equations:

it follows that the increase in volume after combustion equals $y \text{ c.c.} = \text{c.c. of C}_2\text{H}_6$ and again

$x + 2 y = \text{c.c. of CO}_2$ from which x is easily determined.

(6) Experimental Results:

Experiments were carried out at temperatures from 150 to 350°C. The results given in Table I are those for 300 to 350°C only. The analyses have been calculated to nitrogen free.

TABLE I
Catalyst—reduced nickel oxide

Temperature	CO ₂	C ₂ H ₄	O ₂	CO	Analyses of products		
					CH ₄	C ₂ H ₆	H ₂
300	0.6	1.6	0.0	1.3	32.9	47.0	16.6
325	0.8	18.4	0.0	0.8	33.1	29.9	17.0
325	0.4	5.9	0.4	0.8	30.5	40.4	21.6
325	0.4	6.0	0.4	0.9	30.5	40.4	21.4
350	0.0	0.9	0.0	1.3	42.3	34.1	21.4
350	0.9	0.0	1.7	0.0	40.2	36.7	20.5

From Table I, it is evident that above 300°C, methane is formed in addition to ethane by the catalytic decomposition of ethylene. Ethane, however, appears to be stable even up to 350°C; and this is in direct contradiction with Sabatier's statement that with a sufficiently long tube or a sufficiently slow rate ethylene might be decomposed completely into methane, hydrogen and carbon.¹ It was necessary to test the validity of this view as it conflicts with the theoretical conclusions drawn by the writer.

The following experiments establish the stability of ethane up to 360°C in the presence of nickel catalyst.

Ethylene analyzing 95% C₂H₄ was passed back and forth from one gasometer to another over a nickel catalyst heated to 360°C.

The data obtained were as follows:—

Volume of C₂H₄ used—2300 c.c.

Rate—about one liter per hour.

Total time gas circulated—5 hrs. 15 min.

Volume of resulting gas—1800 c.c.

¹ Sabatier: *Compt. rend.*, **124**, 616, 1359 (1897); **131**, 267 (1900).

The experiment was continued on the following day.

Final volume of resulting gas—1800 c.c.

Total additional time gas circulated—3 hrs. 15 min.

Total time—8.5 hrs.

Analysis of final product
(Calculated to nitrogen—free)

CO ₂	C ₂ H ₄	O ₂	CO	CH ₄	C ₂ H ₆	H ₂
0.0	0.0	0.0	0.7	68.2	25.2	5.6

It would be useless, therefore, to attempt to determine the equilibrium constant for the methane, carbon, hydrogen system at or below 360°C, when ethylene is used as the initial system.

B. Methane Equilibrium with Ethylene as the Initial System

The apparatus used was the same as that described in the first paper of the series. The ethylene was prepared in the usual way from absolute alcohol by the dehydrating action of phosphoric acid. The experimental method, however, was varied slightly, in that at the end of an experiment, before the next one was started one-half of the nickel catalyst was removed and replaced by freshly prepared material. It was hoped that in this way, the life of the catalyst would be lengthened. The method of analysis was varied slightly. After a preliminary analysis to determine the absence of ethane, the analysis was repeated using the direct combustion method for the determination of methane and hydrogen.

Preliminary experiments showed that the successive analyses of the product differed after each passage over the catalyst until a point was reached where the analyses remained constant, i. e. until the equilibrium point was reached. This was found to correspond fairly well with the point where further passages produced no further increase in volume. Accordingly the gaseous products were circulated until the change in volume became zero, and were then circulated for two to three hours in addition.

It seemed probable that continued circulation of the gas would lead to lower values for K_p than those calculated upon the basis of amorphous carbon alone. It is inevitable that some graphitization of the carbon will occur when it is subjected to a high temperature over a long period of time. In the actual equilibrium experiments, every attempt was made to reproduce as nearly as possible the same system in the duplicate experiments.

The experimental results follow in Table II.

Table III is a summary, in which the writer's values (C) are compared with the average values of Mayer and Altmayer¹ (M & A). The initial system is specified in each case. To complete the table, calculated values are given (Saunders' Equation for amorphous carbon),² as are also the determined values of Coward and Wilson³ (C & W) for temperatures above 800°C.

670	0.35		0.18		C ₂ H ₄
770	0.12		0.12		CH ₄
850	0.05			0.025	CH ₄
1000	0.02			0.011	C + H
1000	0.02			0.015	C + H
1000	0.02			0.011	CH ₄
1100	0.01			0.006	CH ₄
1100	0.01			0.006	C + H

Table III shows that the results of Mayer and Altmayer are of the same order as those determined by the writer. In addition it shows that the determined results are as a rule lower than the calculated.

The results obtained with ethylene as the initial system probably represent the equilibrium between amorphous carbon, methane and hydrogen more

closely than any of the other values. These results are strictly comparative. In each of these experiments fresh catalyst was used; and the carbon was the amorphous material precipitated by the thermal decomposition of ethylene. It must be admitted, however, that some graphitization of this material would take place over the long period during which the gases were circulated.

Summary

The catalytic decomposition of ethylene was studied and it was found that the special nickel-nickel oxide catalyst was most effective in bringing about this decomposition. At 300°C and higher temperatures, methane is found in the gaseous decomposition products, the percentage of methane following one passage of the gas over the catalyst, increasing with the temperature.

Experiments in which the gaseous products were passed repeatedly over the catalyst proved that ethane was stable in the presence of a nickel catalyst up to 360° C.

Experiments in which the gaseous products of the catalytic decomposition of ethylene (at 500°C and above) were circulated repeatedly over a nickel-nickel oxide catalyst showed that the methane equilibrium should be attained in this manner.

Equilibrium constants for the methane equilibrium at 500 to 770°C were obtained by repeatedly circulating the products of the catalytic decomposition of ethylene over the nickel catalyst. These constants are in general agreement with those obtained by other investigators.

Theoretical: Williams; Eucken; Lorentz and Lande; Polanyi; Harkins; Iliin; Tarasoff.

CONCLUSION.

Note on the Formulation of Adsorption Laws.

Introduction

The great importance of the part played by adsorption phenomena in natural processes is now well recognised, and in consequence of this recognition a large amount of work has been done with a view to discovering the laws which underlie such phenomena, and more particularly to make these laws more concise and readily understandable by expressing them in mathematical form. As a result of this work many adsorption equations are extant, and though none is completely satisfactory, most are valuable as approximations to the truth in a more or less restricted region. In the present paper an attempt has been made to collect in one place the various equations that have been proposed, and to consider in how far they are applicable to actual adsorption systems.

In its strictest sense the word adsorption designates the concentration of one phase at its interface with another, but the filling of pores in the adsorbent, which may accompany true adsorption, is occasionally included in a looser use of the term. In this paper these capillary effects will be considered adsorption just as far as the authors concerned have so considered them, but the adsorption of a gas by a liquid and of a liquid by a liquid will not be discussed.

Nomenclature.

As it is desirable to retain one set of symbols in order to avoid the frequent repetition of definitions, the following will as far as possible be used throughout, irrespective of the actual symbols used by the various authors in the original papers.

Let

m = mass of adsorbent.

v = volume of medium surrounding adsorbent.

X = mass of adsorbate adsorbed by m grams adsorbent.

x = mass of adsorbate adsorbed by 1 gram adsorbent.

s = mass of adsorbate adsorbed by 1 gram adsorbent at saturation.

p = equilibrium pressure of adsorbed gas or vapour.

P = saturation pressure of adsorbed gas or vapour.

c_0 = initial concentration of solution.

c = equilibrium concentration of solution.

θ = temperature Centigrade.

T = temperature Absolute.

t = time.

H = total heat of adsorption.

R = gas constant.

n, k_1, k_2 , etc., constants.

Evaluation of the Quantities.

The experimental determination of most of the above quantities presents no great difficulty, but the evaluation of the amount adsorbed, x , has not always been accurately performed. When adsorption is from the gaseous phase a knowledge of the total volume of the system and the initial and equilibrium

pressures is sufficient to determine x . It seems hardly necessary to add that account should be taken of the volume of the adsorbent, yet this has sometimes been neglected. This method of determining x neglects the volume of the adsorbed gas, but this error is usually quite unimportant.

In the majority of investigations of adsorption from solution x has been taken as equal to $(c_0 - c)w$ or $(c_0 - c)v$, where c denotes the concentration in grams per unit weight or volume, and w and v are respectively the original weight and volume of solution. Williams,¹⁰⁷ however, has pointed out that this calculation of x assumes that the mass or volume of the solvent remains constant during adsorption, and that no solvent is adsorbed. Neither of these assumptions is justifiable, though the error introduced by the former is sufficiently small to be neglected when the solution is very dilute. Williams has further shown that if M is the mass of solution, and concentrations are expressed in grams solute per gram solution, then

$$x_0 = \frac{M}{m} \cdot \frac{c_0 - c}{1 - c},$$

where x_0 is the amount adsorbed calculated on the assumption that no solvent is adsorbed. If x and y represent the true adsorption values of solute and solvent respectively, then

$$x = x_0 + y \frac{c}{1 - c}.$$

In general x and y cannot be determined, but Williams has given two empirical equations from which approximate values may be deduced. This analysis, which leads to a simple explanation of negative adsorption,¹⁰⁹ has more recently been substantiated by Gustafson.⁸²

It is of interest to note that Mecklenburg⁶⁸ has recently proposed a graphical method for the determination of the equilibrium concentration when the amount adsorbed is known.

Classification.

For convenience the problems to be solved may be regarded as the formulation of the following six functions:

- | | |
|-------------------------------------|----------------------|
| 1. The General Adsorption Equation, | $x = \varphi(c, T).$ |
| 2. The Isotherm, | $x = \varphi(c).$ |
| 3. The Isobar, | $x = \varphi(T).$ |
| 4. The Isostere, | $c = \varphi(T).$ |
| 5. Rate of Adsorption, | $x = \varphi(t).$ |
| 6. Heat of Adsorption, | $H = \varphi(x).$ |

I. The General Adsorption Equation

Empirical.

Freundlich²² has developed a method for the representation of adsorption from solution at any concentration and temperature, depending on the use of the equations

$$\log \lambda_t = \log \lambda_0 - k_1 \left(\log \frac{a}{v} \right)^\theta.$$

and

$$\left(\frac{a}{v}\right)_\theta = \left(\frac{a}{v}\right)_0 - S^\theta$$

in combination with his λ equation. (q. v. section II.)

Müller⁷² found that the absorption of water vapour by textile fibres could be expressed by the equation

$$x = (k_1 + k_2 p/P) \sqrt{100 - \theta}$$

This equation is valueless except perhaps over a very limited pressure and temperature range, both the assumptions involved in it—that of a linear relationship between x and p/P and that of zero adsorption at the boiling point—being quite unsound.

Theoretical.

The earliest theoretically derived equation is that deduced by Gibbs.²⁹ In 1874 Gibbs showed thermodynamically that if Γ is the surface excess, σ the surface tension, and μ the chemical potential of the adsorbed substance in solution, then

$$\Gamma = - \frac{d\sigma}{d\mu}$$

Writing $\mu = RT \log(A + k)$ where A is the activity of the solute then

$$d\mu = RT d \log A$$

and

$$\Gamma = - \frac{d\sigma}{RT d \log A}$$

For very dilute solutions $A = c$, and hence $\Gamma = - \frac{c}{RT} \frac{d\sigma}{dc}$.

which is the usual form of the Gibbs equation.

This equation is usually interpreted qualitatively as meaning that if a dissolved substance lowers the surface tension at an interface then it will be positively adsorbed at that interface. Bancroft³ has shown that this interpretation is not a logical conclusion for the interface solid-liquid. Wo. Ostwald⁷⁴ extends the usual interpretation of the equation as follows: "Adsorption will take place whenever there exists at a surface a difference in energy potential which can be decreased by a change in the concentration of the dispersed material bordering the surface."

Amongst other authors who have published proofs of the Gibbs equation are Milner,⁷¹ Harlow and Willows,³⁷ Williams,¹¹¹ Iredale,⁴⁴ and W. Ostwald.⁷³

A deduction of the equation has also been given by Harkins,³⁵ who has shown that

$$\Gamma = - \frac{c}{RT} \frac{d\sigma}{dc} = - \frac{c'}{RT} \frac{d\sigma}{dc'}$$

where c' is the concentration of the solute in the vapour.

Thompson¹⁰⁸ in 1888 deduced the relationship

$$c + \Gamma = ce^{-\frac{1}{RT} \frac{d\sigma}{dc}}$$

which yields the usual Gibbs form on expanding and neglecting higher terms.

That the surface layer cannot be homogeneous with the remainder of the liquid was shown by Warburg,¹⁰⁶ who for sodium chloride solutions obtained a relation for the surface deficit similar to that of Gibbs.

Lewis,⁵⁸ using a somewhat simpler method than Gibbs, has found the equation of electrocapillary adsorption to be

$$\Gamma_{\text{salt}} + \Gamma_{\text{cation}} + \Gamma_{\text{anion}} = - \left[\frac{c}{RT} \frac{d\sigma}{dc} + (a + b) \frac{d\sigma}{d\pi} \right]$$

where a and b are the electrochemical equivalents of anion and cation, and π is the potential difference at the interface. A slight error in Lewis' original proof has been pointed out by Partington.⁷⁶

Porter⁸⁷ is the only author who has derived the equation for concentrated solutions. He finds that

$$\Gamma = - \frac{(1 - ac)^2 c}{RT} \frac{d\sigma}{dc}$$

where c is the ratio of solute molecules to solvent molecules (n/N), and a is Callendar's hydration factor, obtained from the equation

$$\log (P/p) = \frac{n}{N - an}$$

It is of interest to note that Polanyi^{79,80} has shown that for a swelling gel

$$\Gamma = \frac{c}{RT} \frac{d\pi}{dc}$$

where π is the swelling pressure. In a later paper⁸⁶ some results of Loeb have been used to provide experimental confirmation of this equation.

Freundlich²⁸ considers the Gibbs equation to be of limited application, and has stated that the more general equation would be

$$\Gamma = - f(c, T) \frac{d\sigma}{dc}$$

in which all that is known about $f(c, T)$ is that it is positive. The usual form of the equation is obtained by assuming the van't Hoff Laws, and hence is limited with these laws to dilute solutions. Even for dilute solutions, however, Freundlich is doubtful of the soundness of the deduction, since the surface tension depends on factors, such as solvation, which are not considered in the van't Hoff laws. Langmuir,⁵⁶ on the other hand, believes that the deduction is sound for dilute solutions, since the gas laws in some of the derivations,—for example Milner's—are applied only to the interior of the solution. It should be noted, however, that the equation is definitely limited to true solutions, and cannot be applied to colloidal solutions, a point which has been emphasized by Bancroft.⁹ All the deductions of the equation assume the thermodynamic reversibility of the adsorption process, the validity of which assumption may in some instances be in slight doubt.

Many attempts have been made to obtain confirmation of the equation, but the great experimental difficulties have prevented any definite conclusion being reached. Donnan has recently said "the question whether the simplified form of the Gibbs equation yields a sufficiently accurate value for the excess surface concentration can scarcely be decided without further experimental evidence."

According to Langmuir's⁵⁴ theory of adsorption the adsorbate is held by the unsatisfied secondary valences of the adsorbent to form a continuation of the space lattice of the latter, so that the adsorbent forms a true chemical compound with the adsorbate. It is assumed that all molecules striking a surface condense, and that evaporation takes place subsequently, so that adsorption is the equilibrium condition representing the time-lag of condensation over evaporation. Since the force of attraction is much less at the second layer than at the first, molecules will evaporate much more quickly from the second layer, and hence it is to be expected that a monomolecular layer will be exceeded only at high pressures or concentrations. Langmuir's theory is derived specifically for true adsorption at a plane surface, and neglects capillary effects.

A consideration of the dynamic equilibrium between rate of evaporation and rate of condensation leads to a number of equations according to the conditions obtaining at the surface.^{55,57}

(1) The plane surface has only one kind of space lattice.

Then

$$\theta = \frac{k\mu}{\nu + k\mu} = \frac{N}{N_0} \eta$$

where θ is the fraction of the surface covered

ν is the rate at which the gas would condense if the surface were completely covered

μ is the number of moles of the gas striking each square centimetre

per second. From the kinetic theory $\mu = \frac{p}{\sqrt{2\pi MRT}}$

N is Avogadro's Constant

N_0 is the number of elementary spaces per square centimetre

η is the number of moles of gas adsorbed per square centimetre

Under these conditions adsorption should be large and nearly independent of pressure at low temperatures, while at higher temperatures adsorption should be small and proportional to pressure.

(2) The plane surface contains more than one kind of elementary space.

Then

$$\frac{N}{N_0} \eta = \sum \beta_i \theta = \sum \frac{\beta_i k\mu}{1 + k\mu}$$

where β_1, β_2, \dots etc., represent the fractions of the total number of elementary spaces occupied by each kind.

- (3) Amorphous surfaces—all the elementary spaces may be unlike.

$$\frac{N}{N_o} \eta = \int_0^1 \frac{a \mu d\beta}{1 + a\mu}$$

where a is a function of β . In Langmuir's opinion this equation should be true for porous bodies.

- (4) Each elementary space may hold more than one adsorbed molecule.

$$\frac{N}{N_o} \eta = \frac{k_1 \mu + 2k_1 k_2 \mu^2 + 3k_1 k_2 k_3 \mu^3 + \dots}{1 + k_1 \mu + k_1 k_2 \mu^2 + k_1 k_2 k_3 \mu^3 + \dots}$$

This equation may also be expected to hold when adjacent molecules influence each other's rate of evaporation.

- (5) Atomic adsorption—the elementary spaces are occupied by individual atoms of the adsorbate.

$$\eta = \frac{1}{2} \sqrt{\frac{N_o}{N} k \mu}$$

If $\theta \rightarrow 1$, i.e. adsorption is small,

$$\eta \propto \rho^{1/2}$$

- (6) Adsorbed films more than one molecule thick

$$\frac{N}{N_o} \eta = \frac{k}{1/\mu + a + b\mu + c\mu^2 + \dots}$$

where $a = k_1 - 2k_2$

$$b = k_2(4k_2 - 3k_3 - k_1)$$

$$c = 2k_2(6k_2 k_3 - 2k_3 k_4 + k_1 k_2 - k_1 k_3 - 4k_2)$$

This equation shows that at very low pressure η is proportional to μ , but at pressures close to saturation η begins to increase rapidly, and is infinite when saturation is reached.

Langmuir's equations have not yet received adequate experimental confirmation over large pressure ranges, which may perhaps be attributed to the difficulty of expressing the equations in terms of measurable quantities, and also to the fact that the conditions under which they may be expected to hold are ideal rather than readily attainable.

In adducing much evidence in favour of the existence of monomolecular films of oil on water from the experimental work of, amongst others, Milner, Syskovski, and Traube, Langmuir⁵⁶ has made use of a new relation between Γ and c , viz.,

$$\Gamma = c k e^{\frac{\lambda}{RT}}$$

where λ is the decrease in potential energy which occurs when one mole of solute passes from the interior of the solution into the surface layer.

A theory similar to that of Langmuir, has recently been put forward by Frenkel,²¹ while equations of the same type have been obtained thermodynamically by Volmer.¹⁰⁵

Henry³⁰ has developed equations based on the conceptions of surface energy introduced by Hardy and Langmuir. The fundamental assumptions are, first, that the range of action of adsorption forces is comparable with atomic diameters; second, that the impact of a molecule is completely inelastic. By applying to the kinetic equilibrium Jeans' equations for the rate of impact and Langmuir's equation for the rate of evaporation, general equations for the rate of adsorption, the isotherm and the isostere are developed for the adsorption of each of n gaseous components. Examples of these equations are given later.

According to Eucken,¹⁷ there is around an adsorbent an "atmosphere" of adsorbed gas in a state of compression, the density of any layer of this atmosphere varying with its distance from the surface. It is assumed that the adsorbed molecules have no interaction, and that the relation between force (F) and distance (h) is

$$F = - \frac{k}{h^{\mu+1}}$$

where μ is a constant. In a manner similar to the derivation of the barometric height formula the equation representing the adsorption of a perfect gas by a plane surface of area O is obtained in the form

$$X = OC_{\infty} \int_{\delta}^{\infty} \left(e^{-\frac{Fh}{RT}} - 1 \right) dh$$

where δ is the mean molecular diameter, and C_{∞} is the number of moles of gas in unit volume at a distance from the surface corresponding to zero attractive force. By evolving in series and integrating an approximate solution is obtained

$$X = \frac{O\delta C_{\infty} e^{\frac{k_2}{\mu T}}}{\frac{k_2}{\mu T} - k_3}$$

Other equations are given for the adsorption of a perfect gas by a segmented surface, the adsorption of a real gas by a plane surface, and the adsorption of a vapour by a segmented surface. In a more recent paper Eucken¹⁸ has re-derived those equations making use of Boltzmann's relation between the potential energy of a single particle and its distance from the surface. Throughout this work it is assumed that $\mu = 3$, which is hardly in agreement with modern opinion.¹⁶ Nevertheless, the theory is in good agreement with experimental data; the same value for k_2 is obtained whether it is calculated from (1) the temperature coefficient of gaseous viscosity, (2) van der Waals' theory or (3) the heat of adsorption.

Polanyi³⁶ has adversely criticised Eucken's theory, and has concluded that it is not applicable to any of the markedly curved isotherms.

Lorentz and Lande³⁹ believe that Debye's work on the dipolarity of molecules is opposed to the conception of a purely molecular force of adsorption, and they conclude in contradistinction to Eucken, that adsorption

potential should in general vary with temperature. For the temperature range in which x varies as p they deduce the equation

$$X = \frac{O\delta C_{\infty} \epsilon^{k/T}}{2\mu \left(\frac{k}{T}\right)^2},$$

which is very similar to that obtained by Eucken. It is also shown that the apparent independence of potential on temperature found by Eucken, cannot be adduced as evidence against the dipolar molecular theory.

Polanyi⁸¹ by considering with relation to the Third Law the heat and free energy of wetting has deduced that at low temperatures an adsorption system behaves as an ideal concentrated solution, whilst with increasing temperature the behaviour gradually approaches that of a dilute solution. By assuming that the adsorbed layer is highly compressed by the molecular forces and that the "exponential" equation holds, he has concluded that the molecular force varies as the distance. (cf. Edser¹⁶).

In a later paper Polanyi,⁸² still assuming a highly compressed layer more than one molecule thick, has shown how to calculate the adsorption at any temperature and pressure if one isotherm is known. As a result of the compression a vapour will exist in the adsorption layer in the liquid state; if it is assumed that the internal pressure of this liquid is identical with that of the liquid in bulk then from thermodynamics it follows that $\epsilon_x = RT \log P/p$ where ϵ_x is the adsorption potential at a distance i , corresponding to an amount x adsorbed. If now an isotherm is known for any temperature below the critical, the relation $\varphi_i = x/\delta_o$ where δ_o is the density of the compressed layer, assumed equal to that of the liquid, and φ_i is the volume of the adsorption space to a distance i from the surface, allows of the plotting of a curve showing the relation between ϵ and φ . It being assumed that this relation does not vary with the temperature, a curve can be drawn showing ϵ_i against δ_i , provided the equation of state of the adsorbed substance is known. This calculation of δ_i varies according as (1) the gas is condensible, (2) the gas is not so condensible (3) the gas is in the transition region between (1) and (2). Lastly a curve can now be drawn showing δ_i against φ_i , and mechanical integration of this curve gives the amount adsorbed, since

$$x' = \int_{\varphi}^{\varphi_{\max}} \delta \cdot d\varphi - d_x \cdot \varphi_{\max}$$

where x' is the adsorption excess, d_x is the density of the free gas space, and φ_{\max} is the volume of the total adsorption space.

According to this theory the adsorption excess isotherm is divisible into a first part where the ideal gas laws are applicable and x varies as p , a second part where the a/v^2 of van der Waals' equation predominates and the compressibility decreases more slowly than $1/p$, and a third part where van der Waals' b predominates and the compressibility decreases more quickly than $1/p$. The theory also indicates that the saturation value should vary with the temperature, and in a later paper Polanyi⁸³ claims superiority of his theory over that of Eucken on this account.

Calculations according to the theory are in excellent agreement with experimental data, and this agreement is regarded as proof of the validity of the assumption that the adsorption potential is independent of the temperature.⁵³ Assuming the electrical origin of attraction, Polanyi therefore concludes that the cause of cohesion is a deformation of the molecules to bring opposite charges as near as possible.

The theory has been extended to solutions⁵⁴ but there is not sufficient suitable experimental evidence to allow of the verification of this extension; qualitatively, however, it is in agreement with Freundlich's rule that substances which are strongly adsorbed from solution permit only of weak adsorption from solutions in which they act as solvents.

Berenyi^{6,7} has developed two new methods of calculating the $\epsilon - \varphi$ diagram, one by the use of the pressure-density tables of Amagat, the other depending on the Nernst rule of corresponding states. The latter method can be applied only at temperatures between 6 and 1.4 times the boiling point, to substances whose boiling points lie between 170° and 400° A.

As stated before, Lorentz and Lande⁵⁹ disagree with the assumption of temperature independence of potential, but they have shown that Polanyi's theory is in agreement with the application of the theorem of corresponding states to adsorption in the $p - \theta$ region where Henry's Law holds but where the pressure is not greater than the critical pressure and the temperature not less than the critical temperature.

Polanyi's theory is well supported by the experimental data tested, yet it is based on three unproved assumptions; (1) It is assumed that the potential ϵ and with it van der Waals' a is independent of the temperature. (2) It is assumed that the potential is independent of whether the remaining space is empty or not. (3) It is assumed that the equation of state is applicable to an adsorbed gas.

Berl and Schwebel⁹ have combined Polanyi's equations with the "exponential" equation to find the quantity of steam required to expel a gas from an adsorbent. The agreement with experiment is excellent.

Considering the forces of adsorption to be of electrical origin Iliin⁴⁸ has obtained, by a method similar to that used by Eucken, a complicated expression for the amount adsorbed x in terms of the surface, temperature, etc., and a number of electrical quantities. This equation requires that the graph of $\log \left(x \cdot \frac{\epsilon - 1}{\epsilon} \right)$ where ϵ is the dielectric constant of the adsorbed gas, plotted against $\frac{\epsilon - 1}{\epsilon}$, should be a straight line. In this manner the equation is confirmed by the experimental results of Homfray and Titoff.

II. The Isotherm

A typical isotherm for adsorption from the gaseous phase is shown in Fig. 1. From this curve it is obvious that dx/dp approaches zero as p increases, d^2x/dp^2 being negative. The adsorption of vapours may be repre-

sented by one or other of the two curves of Fig. 2. For both these curves dx/dp increases as the partial pressure approaches its saturation value, but for curve 2 d^2x/dp^2 is positive, whilst for curve 1 d^2x/dp^2 passes from negative to positive values. Little information is available for the construction of isotherms illustrating adsorption from the liquid phase over any extended range of concentration, but what there is indicates that the curve is of the form shown in Fig. 3. It should be noted, however, that this curve shows the variation of x_0 not x , with the concentration.

From a consideration of the curves shown above it seems clear that one equation cannot be expected to represent these various types of isotherms. *Empirical.*

The equation $x = kc^{1/n}$, which is usually but erroneously called the "exponential," is perhaps the best known of all the equations which have been proposed to represent an adsorption isotherm. According to Firth,¹⁹ De Saussure⁹⁴ in 1814 was the first to apply this equation to the adsorption of gases; its application was extended to solutions by Boedecker¹⁰ in 1859, and in more recent years it has been used by hundreds of workers.

Experiment has shown that the exponent $1/n$ is always less than 1: hence dx/dc decreases as c increases, and d^2x/dc^2 is negative. Thus the equation may represent the isotherm for a gas shown in Fig. 1, but cannot represent any part of curve 1 of Fig. 2, while it is applicable only to the first portions of the other two isotherms. It would seem at first glance, therefore, that this equation does not agree very well with experimental data, but it should be noted that it can be applied to most adsorption phenomena in the low pressure or low concentration region, and as much of the experimental work which has

been carried out did not extend beyond this region, the equation was found to be of very general applicability. Above the region in which the equation may safely be used $1/n$ decreases with increasing pressure or concentration.

Consideration of a large amount of data has shown that the smaller the adsorbability of the gas the greater is $1/n$, a conclusion which agrees with Seeliger's¹⁰⁰ observation that $1/n \propto 1/T_c$ where T_c is the critical temperature of the adsorbate. It is also generally found that $1/n$ increases with increasing temperature; in fact, Berl and Schwebel⁹ have shown from Polanyi's theory that $1/n \propto T$. Williams,¹¹² in a critical discussion of much data, has shown that at low concentrations $1/n$ approaches 1, i. e. the system obeys Henry's Law. All of these observations may be coordinated in the statement that the smaller the amount adsorbed the more nearly does $1/n$ approach 1. It is also found that $1/n$ increases with molecular complexity, runs parallel to the strength of solute acids, and is independent of the degree of dispersion of the adsorbent. k , on the other hand, increases with the degree of dispersion of the adsorbent and varies inversely as $l^{1/n}$, where l is the solubility of the solute.

Schmidt and Hinteler,⁹⁹ in applying the equation to organic vapours used it in the form $x = s(p/P)^{1/n}$, while a similar modification has been used by McGavack and Patrick,⁶⁷ viz $\frac{v}{\sigma^{1/n}} = k(p/P)^{1/n}$, where v is the volume of condensed vapour and σ is the surface tension.

According to Gurwitsch⁸¹ the equation $x = k_0 + k_1 c^{1/n}$ agrees better with the results of experiment than the usual form, but the superiority of this equation has been disputed by Kolosovski.⁴⁹ Ostwald and Izaguirre⁷⁵ have pointed out that the curves are identical, the only difference being in the disposition of the axes of reference.

It was found by Kroecker⁵¹ that $dx/dm = \frac{\lambda(a-x)}{v}$ where a is the original amount of solute and λ is a constant. From this result Freundlich^{22,28} deduced his "λ equation"

$$\lambda = \frac{v}{m} \log \frac{a}{a-x}$$

in which λ is independent of m , but is a function of a/v or C_0 . He also found that

$$\lambda = \frac{v}{m} \log \frac{a}{a-x} = k_1 \left(\frac{a}{v} \right)^{k_2}$$

from which by expanding in series the "exponential" equation can be derived. In conjunction with Gibbs' equation (q.v.) it yields an expression for the variation of surface tension with concentration which agrees well with experiment. The λ equations have been criticised by McBain,⁶⁴ who concludes the system of λ formulae introduced recently by Freundlich to represent the amount of adsorption does not lead to any definite number characteristic of each set of substances, and further, its results are irreconcilable with each

other and with experiment. It should be noted, however, that in his argument McBain erroneously used zero instead of 2 as the limit when $a/c \rightarrow 1$ of the expression

$$\frac{d \log c}{d \log X/m} = \frac{(a - c) \log a/c}{(a - c) - c \log a/c}$$

Nevertheless, the λ equation is not unexceptionable, as is shown below. We have

$$\lambda = \frac{v}{m} \log \frac{a}{a-X}, c_0 = \frac{a}{v}, c = \frac{a-X}{v}$$

$$X = mx = v(c_0 - c)$$

Hence
$$\lambda = \frac{x}{c_0 - c} \log \frac{c_0}{c} = \frac{x}{c_0} \frac{\log c_0/c}{1 - c/c_0}$$

and
$$\frac{d \log \lambda}{d \log c} = \frac{d \log x}{d \log c} - \frac{1}{\log c_0/c} + \frac{c/c_0}{1 - c/c_0}$$

Now if λ is independent of c when c_0 is constant, as is claimed, then

$$\frac{d \log \lambda}{d \log c} = 0$$

and therefore

$$\begin{aligned} \frac{d \log x}{d \log c} &= \frac{1}{\log c_0/c} - \frac{c/c_0}{1 - c/c_0} \\ &= \frac{1}{-\log c/c_0} - \frac{c/c_0}{1 - c/c_0} \\ &= \frac{1}{(1 - c/c_0) + \frac{1}{2}(1 - c/c_0)^2 + \frac{1}{3}(1 - c/c_0)^3 + \dots} + 1 - \frac{1}{1 - c/c_0} \\ &= \frac{1}{1 - c/c_0} - \frac{1}{2} - \frac{1}{12} (1 - c/c_0) - \dots + 1 - \frac{1}{1 - c/c_0} \\ &= \frac{1}{2} - \frac{1}{12} (1 - c/c_0) - \dots \end{aligned}$$

where all succeeding terms are negative. Now if adsorption is positive $c < c_0$

and therefore $0 < (1 - c/c_0) < 1$. Hence $\frac{d \log x}{d \log c}$, which is the $1/n$ of the exponential equation, has, for positive adsorption, a maximum value of $\frac{1}{2}$. This is quite contrary to experience. Moreover this value is obtained when $1 - c/c_0$ approaches zero, that is, when the adsorption is small, whereas it has already been mentioned that for small adsorption $1/n \rightarrow 1$.

Rakovski^{88, 89} found that his isotherms for the absorption and desorption of water by starch could be adequately represented by the equation

$$p - k_1 = k_2 \sin (\sigma - k_3) + k_4 \sin (\sigma - k_5)$$

where
$$\sigma = \frac{x}{s} \cdot \pi$$

This equation is discussed with relation to the two solution theory of gel structure. The same author⁹¹ found that the adsorption of metallic hydroxides from solution by starch could be represented by the mass-action equation

$$\frac{x}{(M - x)(a - x)} = k$$

where M and a were the original amounts of starch and metallic hydroxide.

For the adsorption of gases the equation

$$x = k_1 p + k_2 p \log p$$

has been used by Kayser.⁴⁸ The curve of this equation is of the form of curve 1, Fig. 2.

Schmidt⁹⁶ used the equation $\log \frac{s}{s - x} = kc^{1/2}$, which agreed well with his experimental data.

Homfray⁴⁰ found that the equation $x = k_1 \log p + k_2$ which had previously been used to represent the adsorption of iodine and dyestuffs from solution, was quite inadequate as a representation of her data for gases.

Trouton¹⁰⁴ used the equation $(s - x)^2 = k(P - p)$ to express his results for the adsorption of water by cotton. From an examination of this equation it is obvious that it is applicable only to the upper portion (convex to the pressure axis) of the typical curve for a vapour.

Theoretical.

There have been a number of attempts to place the "exponential" equation on a sounder basis than that of mere empiricism, and some of these have met with a fair amount of success. Robertson⁹⁸ deduced the equation by considering adsorption to be a chemical reaction of the type $n_1 A + n_2 B \rightleftharpoons n_3 AB$ and applying the Law of Mass Action, making certain assumptions as to the concentration of the adsorbent. This deduction has been criticised by Freundlich.²⁴ Kolthoff,⁵⁰ regarding the adsorption of ions by solids as analogous to the exchange of bases in permutite, has obtained the equation in which k depends on the solubility product of the two difficultly soluble salts and $1/n$ is inversely proportional to the valency of the adsorbed ion. What is perhaps the soundest deduction is due to Henry,³⁹ who has derived the equation by a consideration of the free surface energy changes of the bare and covered surfaces and by applying the Gibbs equation (q. v.). In his derivation $1/n$ has the theoretical significance of the ratio osmotic work done in the adsorption of x moles to total work in the adsorption of x moles, from which it follows that $1/n$ is always less than 1, and increases with increasing temperature.

Ostwald and Izaguirre⁷⁶ consider adsorption from solution to be essentially the adsorption of a layer of solution, so that two solvent layers are obtained between which the solute is distributed. By assuming that the amounts of solute and solvent adsorbed are given by the "exponential" equation, these authors deduce equations for the conditions:

- (1) When the adsorption of solvent is neglected.
- (2) When solvent is directly adsorbed.
- (3) When solvent is found in the adsorbed phase as a result of the solvation of the solute.
- (4) When solvent is found in the adsorbed phase according to (2) and (3).

On the assumption that adsorption may be attributed to the forces of physical attraction, chemical attraction, and physico-chemical attraction Gurwitsch⁸¹ has shown that for solutions the equation to the isotherm must be $\varphi(x) = k + \psi(c)$. It is of interest to note that Gurwitsch's empirical equation (q. v.) has been derived by Zacharias¹¹⁶ from the Nernst-Fick diffusion law, on the assumption that the resistance to diffusion varies as a power of the concentration.

Stadnikoff¹⁰¹ distinguishes between four different types of adsorption, viz:

- (1) Solution adsorption, which obeys Henry's Law. For example the distribution of potassium chromate between water and gelatin.
- (2) Chemical adsorption, quantitatively expressed by the Law of Mass Action, for example the adsorption of acid by aniline black.
- (3) (1) and (2) acting together.
- (4) Exchange adsorption, as when an aniline salt adsorbs an acid other than that already combined in it. For such phenomena the ratio of the amount of the one adsorbed acid to its final concentration is directly proportional to the corresponding ratio for the other acid.

These considerations put forward by Stadnikoff are applicable only to solutions, and it is doubtful if all the phenomena considered can properly be included as adsorption.

Pavlov⁷⁷ has developed equations for chemical adsorption, distribution adsorption, and capillary adsorption, and has indicated how the three types may be distinguished. The use of the method is exemplified by its application to a study of the adsorption of acetic acid by charcoal.

Reichinstein⁹² from his displacement principle has obtained an equation of similar form to those of Langmuir. Reichinstein's equation is, however, definitely limited to the isotherm.

The only theoretical treatment of the phenomena of hysteresis is that of Duhem,¹⁵ whose mathematical analysis however, is too general to allow of quantitative comparison with existing data. Qualitatively his conclusions are in good agreement with the results of van Bemmelen.

Schmidt's⁹⁵ first equation for adsorption from solution

$$\log \frac{s}{s-x} - k_1 x = k_2 c,$$

was derived by an application of the mass action law, together with a number of assumptions of doubtful validity with regard to the physical conditions at the interface. The equation neglects the adsorption of solvent, and Arrhenius² has shown that the derivation is unsound for values of x approaching s . It has also been criticised by Marc.⁶¹ The agreement with Schmidt's experimental data is fair, but probably no better than that of his empirical equation.

Arrhenius' ² equation $\log_{10} \frac{s}{s-x} - .4343 \frac{x}{s} = kc$, is very similar to that

of Schmidt. According to this equation, however, $\frac{d \log x}{d \log c}$, i.e. $1/n$ of the exponential equation, approaches the value $1/2$ as x decreases, which is contrary to the experimental evidence. It has been criticised by Schmidt⁹⁷ and Marc.⁶²

By considering adsorption as a dynamic equilibrium between solute precipitated and solute dissolved, and assuming as before that the reaction coefficient varies with the amount adsorbed, Schmidt^{96, 97} derived a second equation

$$\left(\frac{a-x}{v}\right)s = Cs = ke^{\frac{A(s-x)}{s}} \cdot x.$$

This equation yields a curve of the form shown in Fig. 1, and reduces to Williams' equation if s is replaced by an arbitrary constant. It also was adversely criticised by Marc,⁶² following which Schmidt⁹⁸ gave two new derivations similar to the first but depending on the known laws of diffusion in solution. Realising, however, the error involved by neglecting the adsorption of solvent, Schmidt⁹⁹ has stated that the equation should not be used as a representation of an adsorption isotherm.

From a few simple assumptions Iliin⁴² has obtained the equation $x = s(1 - e^{-kp})$, which is related to the equations of Schmidt, Arrhenius, and Langmuir.

Williams^{118, 114} obtained thermodynamically the equation to the isotherm $\log x/c = k_1 + k_2x$. In the derivation of this equation higher terms of a series are neglected, so that it must be regarded as a first approximation only. Williams has shown that it agrees well with experimental data at low pressures, while Briggs¹¹ has shown that it may be successfully applied to gases above their critical temperatures at pressures up to 100 atmospheres, if a correction is made for the gas (obeying Boyle's Law) compressed in the pores of the adsorbent. Provided $1/x > k_2$, Williams' equation gives a curve of the type shown in Fig. 1.

The general equation to the isotherm obtained from Henry's⁸⁹ theory (q. v.) is not soluble, but for the adsorption of a single gas the equation becomes $x = k_1p \left(1 - \frac{x}{k_2}\right)^{k_3}$, which for small pressures is identical with Williams' equation.

The relationship between a number of the isothermal equations has recently been demonstrated by Gorbatschew,⁸⁰ who, by superimposing various simplifying assumptions on a few general relationships, has derived the equations of Langmuir, Reichinstein, Schmidt, Williams, and Henry, together with Freundlich's λ equations, and the "exponential" equation.

The lack of a complete mathematical interpretation of the isotherm has recently been expressed by McBain,⁶⁶ who believes that the "exponential" equation is still the best representation of the existing data.

III. The Isobar

Empirical.

Kayser⁴⁸ found that if v is the volume of adsorbed gas at temperature θ , then approximately, $v = k_1 + k_2 \theta$

Ostwald⁷⁸ has used two equations, viz.

$$x = x_0 + \frac{k}{T} \quad \text{and} \quad x = x_0 + \frac{k}{T^3}.$$

Freundlich^{25, 28} found that for not too high temperatures and pressures the $\log x$, $\log p$, curves at different temperatures spread out in a fan shaped diagram. In these circumstances

$$\log x_\theta = \log x_0 - (\zeta - \xi \log p)\theta$$

where ζ and ξ are constants. By comparing this equation with the isobar obtained from the exponential equation by differentiating with respect to θ and putting $dx/dp = 0$, it is found that

$$\xi = \frac{d1/n}{d\theta} \quad \text{and} \quad \zeta = -\frac{dk_\theta}{k\theta d\theta}$$

At higher temperatures $1/n$ approaches 1, and hence $\xi = 0$, the equation to the isobar becoming $\log x_\theta = \log x_0 - \zeta\theta$. This equation has also been used for adsorption from solution.

Theoretical.

Williams^{113, 114} equation to the isostere (q. v.) is

$$\log \frac{RTx}{p} = \frac{k_1}{T} + k_2$$

If p is constant we obtain for the equation to the isobar

$$\log x = \frac{k_3}{T} + k_4 - \log T$$

Iliin⁴² has recently obtained a relation between x and T of the form

$$x = k_1 e^{-k_2 \sqrt{T}}$$

which gives fair agreement with the experimental data of Homfray and Titoff.

IV. The Isostere

Empirical.

By differentiating $x = kp^{1/n}$ with respect to θ and putting $dx/d\theta = 0$, Freundlich²⁸ obtained for the equation of the isostere

$$\frac{d \log p}{d\theta} = n (\zeta - \xi \log p)$$

where ζ and ξ are the same constants that appear in Freundlich's equation for the isobar. As before at higher temperatures $\xi = 0$ and thus the equation becomes

$$\log p\theta = \log p_0 - \xi\theta$$

As a representation of her experimental data Homfray^{40, 41} successfully used the Ramsay-Young vapour pressure law

$$\frac{T_0}{T_1} - \frac{T_0'}{T_1'} = R(T_0 - T_0')$$

where T_1 and T_1' are the absolute temperatures corresponding to two selected pressures on any one isostere, and T_0 and T_0' are the temperatures at which any saturated vapour exerts the same pressures. It is shown that this relationship may be derived from Bertrand's empirical vapour pressure formula

$p = k_1 \left(\frac{(T - x)}{T} \right)^{k_2}$, which itself expresses the isostere results. It is of interest

to note that the Ramsay-Young equation may be derived from the Clapeyron equation by assuming that the molecular latent heat is independent of temperature. It may also be derived from van der Waals' equation.

Theoretical.

By equating two expressions for the change of energy consequent to the adsorption of 1 mole of gas obtained from the kinetic theory and the ordinary theory of attraction, Williams^{113, 114} deduced the equation of the isostere to be

$$\log \frac{x}{c} = B + A/T$$

where B and A are independent of temperature. Although this equation is an approximation it is in good agreement with experimental data. In the deduction it is assumed, first, that the kinetic energy of a molecule is unchanged by adsorption, second, that $a(\delta - \sigma)$ is independent of temperature, where a is the area of the adsorbent, δ is the thickness of the adsorption layer, and σ is the diameter of an adsorbed molecule. From a long theoretical discussion a method is derived of placing the internal cohesion of gases, and of evaluating the range of molecular action and the thickness of the adsorbed layer. The values thus obtained are in good agreement with those obtained by other methods.

The isostere equation obtained from Henry's³⁹ theory (q. v.) is identical with that of Williams. Henry has also indicated a method of deriving this equation from Perrin's radiation hypothesis.

V. Rate of Adsorption

Whilst values from a few seconds to as many years have been recorded as representing the time required for the attainment of equilibrium in an adsorption system, there is a large amount of evidence to show that equilibrium is reached in a finite time. The curve showing the relation between x and t should therefore be of the form shown in Fig. 1, dx/dt decreasing with increasing t , and becoming zero at a finite value of t .

Empirical.

The equations of Mills and Thomson⁷⁰ and Mills and Takamine⁶⁹ are probably the first to be proposed for the representation of the rate of adsorp-

tion. These investigators found that the rate of adsorption of dyes from solution by textile fibres could be expressed in one of the forms:

$$y = A\alpha^t \pm B, y = A\alpha^t, \text{ or } y = A\alpha^t \pm B B^t$$

where y is the per cent dye remaining in the bath after time t , $A \pm B$ is the initial amount of dye (taken as 100), and α and B are constants.

For the adsorption of gases Bergter⁸ has used the equation

$$x = \frac{k_1 t}{a + t} + \frac{k_2 t}{b + t}$$

as well as exponential equations of the type $x = k_1 + k_2 e^{k_3 t} + k_4 e^{k_5 t}$. Similar equations have also been used by other authors, including Rakovski,⁹⁰ and Bateman and Town.⁵

The best-known rate equation is probably that first used by Lagergren⁵² $\frac{dx}{dt} = k(x_\infty - x)$, where x_∞ is the final value of x . This equation does not conform with the general requirements of the rate equation, and Gustaver³³ has pointed out that it is inapplicable to high concentrations, since it assumes the constancy during adsorption of the concentration.

Pickles⁷⁸ has used both for adsorption from a gas and from a liquid the equation

$$k = \frac{1}{t_2 - t_1} - \log \frac{a - x_1}{a - x_2} - .4343 \frac{x_2 - x_1}{a}$$

where a is the original amount of adsorbate.

From their data, which are probably the most accurate figures known for the rate of adsorption of a gas, Burt and Bangham¹² have successfully used the equation $\log x = k_1 \log t + k_2$. Beyond the range in which this equation is applicable Bangham and Sever⁴ have shown that the equation

$$\log \frac{x_\infty}{x_\infty - x} = k_1 t^{k_2}$$

may be used.

Zacharias,¹¹⁷ using an equation due to Korner found that the rate of adsorption from solution was given by

$$\frac{dx}{dt} = k(c_0 - x)(c - x)$$

Freundlich^{26, 27} and his co-workers have represented the rate function by the "equations of negative auto-catalysis," either

$$\frac{dx}{dt} = 2kt(1 + bx)(1 - x)^2 \quad \text{or} \quad \frac{dx}{dt} = 2kt(1 + bx)(1 - x)$$

They have further found that the variation of k with temperature is given by Arrhenius' equation

$$\log k = -\frac{k_1}{T} + k_2,$$

and its variation with concentration by the equation $k = k_1 x^{k_2}$

Dietl¹⁴ has used these equations in preference to those of Zacharias and Lagergren and in preference to the equation

$$\frac{dx}{dt} = \frac{k(a-x)}{x},$$

and he has shown that one of them can be derived from the Nernst-Brunner diffusion equation

$$\frac{dx}{dt} = \frac{O D(a-x)}{\delta},$$

if δ , the diffusion layer, changes with time in the sense found by Moderstein and Fink for the kinetics of the contact process for the manufacture of sulphuric acid.

Recently Davis and Eyre¹⁵ have claimed that for colloids the rate curve is discontinuous, each portion being represented by an equation of the type

$$x = k_1 t + k_2 t^2 + k_3 t^3$$

The rate of evaporation from the very ill-defined system soil-water has been investigated by several workers, and various empirical formulæ have been proposed. A thorough analysis of this work has been made by Fisher,²⁰ who finds that the rate curve is discontinuous.

It will be noted that a number of these equations do not conform with the general requirements of the rate equation, and that for some of them $x \rightarrow \infty$ as $t \rightarrow \infty$, which renders them applicable to a limited region only.

Theoretical.

By considering an adsorption system as a solid solution, and assuming the applicability of Fick's Law, McBain⁶⁵ derived an equation to represent the rate of adsorption. From a consideration of the properties of this equation, however, McBain concluded that any theory of arrested diffusion was untenable.

Marc,⁶³ assuming that the rate of adsorption in solution depends on the attractive force, the osmotic pressure of the solute, and the kinetic energy of the adsorbed molecules, writes

$$dx/dt = k_1 x^{-k_1} - k_3 + k_2 (a - x)$$

where the first term represents the effect due to the attractive force, the second term the kinetic energy of the adsorbed molecules and the third term the osmotic pressure of the solute. For values of x not too near x_∞ , an approximate solution is given by

$$\frac{x^{k_1+1}}{t} (2x_\infty^{k_1} + k_2 x^{k_1}) = k_3$$

This equation has also been used by Arendt.¹

By assuming that the amount of adsorption is proportional to (1) the free surface, and (2) the total amount of adsorbate in the gaseous or liquid phase, Gustaver³³ obtained the equation

$$k = \frac{1}{t(a-x)_\infty} \left(\log \frac{a-x}{x_\infty-x} \cdot \frac{x_\infty}{a} \right)$$

for adsorption from a liquid, a similar equation obtaining for the adsorption of a gas. These equations can also be deduced from Langmuir's theory.

Henry,⁸⁹ from the theory already discussed, has deduced the general equation for the rate of adsorption of one component (r) from a mixture of n gaseous components to be

$$\frac{dx_r}{dt} = k_1 p_r \left[1 - \frac{x_1}{s_1} - \frac{x_2}{s_2} \dots \dots - \frac{x_n}{s_n} \right]^{k_r} - k_2 x_r$$

Iliin⁴² has obtained an equation $\frac{dc}{dt} = k_1 e^{-k_2 t}$ which agrees well with experimental results. This equation is of the same form as the empirical equations of Rakovski and Bergter.

VI. Heat of Adsorption

In this section, following Williams,¹¹⁰ h is used to denote the heat of adsorption, defined as the ratio of the heat evolved to the gas adsorbed when only a very small quantity of gas is adsorbed; the total heat of adsorption will be, in general, $H = \int_{x_1}^{x_2} h_x \cdot dx$. This integral can usually be obtained only by graphical or mechanical integration.

Empirical.

Whilst there are many early observations of heat effects accompanying adsorption, Freundlich²⁵ was the first to formulate equations for the heat of adsorption, distinguishing two kinds:

(1) Integral heat of adsorption, corresponding to heat of solution, evolved when a gas is brought into contact with just sufficient adsorbent to take it up.

(2) Differential heat of adsorption, evolved when one equilibrium condition is transferred to another. According to Freundlich this transformation can take place either isothermally (x constant) or isopneumatically (p constant). Combining the Clapeyron equation with his empirical equation to the isostere (q. v.) he obtained the equation

$$-h_x = \frac{nRT^2}{22410 \log_{10} e} (\zeta - \xi \log p)$$

for the differential heat of adsorption under isosteric conditions. Williams¹¹⁰ has criticised the above classification as being confusing and erroneous, and has pointed out that the Clapeyron equation really refers to $(h)_{p,T}$. Arrhenius,² on the other hand, believes that the Clapeyron equation can be applied in the region where h does not vary greatly with p , since he supposes the adsorbate to behave as a liquid under its own saturated vapour.

Combining the Clapeyron equation with Bertrand's vapour pressure equation, Homfray^{40, 41} obtained the equation $(h)_{p,T} = \frac{100xT}{T-x}$ where x is the amount of adsorbate expressed in per cent of adsorbent.

Lamb and Coolidge⁵⁸ from a study of the heat of adsorption of eleven organic vapours find that the heat of adsorption is given by $h = k_1 x^{k_2}$ where h

is the heat of adsorption per normal cubic centimetre of vapour and x is the number of cubic centimetres adsorbed. Since k_2 is approximately 1, the heat of adsorption decreases but slightly with increase in x . It is also found that the difference between total heat of adsorption and heat of evaporation is nearly constant for all liquids, and that these differences are closely proportional to the heats of compression under high pressures.

Katz and Holleman⁴⁷ have recently shown that for water and carbon from $x = 5$ to 81% (saturation = 93%) the variation in h is of the same order as the variation in free energy obtained from the equation

$$A = \frac{1252}{18} \log_{10} p/P.$$

Theoretical.

To Williams^{108, 110, 111} is due the exact definition of h under different conditions, as follows:

(1) At equilibrium $(h)_T$; where adsorption proceeds with the vapour phase constantly in equilibrium with the adsorbed phase.

(2) At constant pressure, $(h)_{p,T}$; where the gas is adsorbed at constant but not necessarily equilibrium pressure.

(3) At constant volume $(h)_{v,T}$; where the total volume of the system is constant and the gas is adsorbed with a fall in pressure.

In a later paper¹¹¹ expressions are developed thermodynamically for $(h)_T$, $(h)_{p,T}$, and $(h)_{v,T}$. From these equations it follows as a first approximation that $(h)_{p,T} = (h)_{v,T} + RT$. The application of the equation for $(h)_{p,T}$ to Titoff's measurements leads to the conclusion that the surface area alters during adsorption.

Where a vapour is adsorbed as a liquid it is shown that $(h)_{p,T}$ is given approximately by the relation

$$(h)_{p,T} = RT^2 \left(\frac{\delta \log p/P}{\delta \log T} \right)_x$$

Expressions are also developed for the heat of immersion of a powder in a liquid when

(1) The powder is free from the adsorbate before immersion

(2) The powder is partially saturated before immersion

Corresponding to these two expressions two others are developed for similar conditions, but allowing for a change in the surface area of the adsorbent.

By finding the amount of work entailed in the formation of a single layer of gas on an adsorbent and integrating by reduction Eucken^{17, 18} has obtained a simple equation which when coupled with the Second Law yields the simple result that the heat of adsorption per mole of gas is equal to the adsorption potential ϵ , defined as the amount of work involved in bringing a mole of gas from an infinite distance to the surface. Thus $H = \epsilon = Rk_2$, where k_2 is obtained from Eucken's adsorption equation (q. v.) for the total amount adsorbed. In a further discussion in which it is assumed that the adsorbing force is molecular attraction it is deduced that k_2 should vary as the square root of

- (1) The boiling point of the gas
- (2) van der Waals' a .
- (3) The heat of evaporation of the adsorbed gas.

These expectations were realised.

By considering the orientation of the molecules resultant on dipolarity Lorentz and Lande¹⁵⁹ have also found the adsorption potential to be equal to the heat of adsorption. They have also shown from the theorem of corresponding states that the heat of adsorption per mole $H = R\Theta T_c$, where Θ is a universal constant $= \frac{k}{T_c}$, k being the constant of their adsorption equation (q. v.). k may also be obtained from a knowledge of the dipolar moment of the molecule. This application of the theorem of corresponding states only applies in the p, θ region where Henry's Law holds, and where $p \gg p_c$, and $\theta < \theta_c$.

Polanyi,⁸² making the assumptions previously considered, found that $\epsilon_x = -RT \log p/P$, but differing from Eucken, set the heat of adsorption in a non condensible region $H = \epsilon_x + \sigma_x$, where σ_x is the molar heat of compression, equal to $a\delta$, where a is van der Waals' constant and δ is the density of the gas. For a gas in the condensible region the molar heat of evaporation (λ) must also be added, so that $H = \epsilon_x + \sigma_x + \lambda$.

On the assumption that the adsorbed vapour is compressed by the molecular forces Harkins³⁶ deduced thermodynamically that for a saturated vapour $-H = E_s - E_i + \lambda_v$ where $-H$ is the heat of adsorption of sufficient vapour to form a liquid layer covering the solid surface,

λ is the heat of evaporation of unit volume,

E_s is the total surface energy of the solid,

and E_i is the total energy of the interface formed by the adsorption.

This equation, which really yields the heat of immersion, is deduced on the assumption that the surface area of the liquid is negligible in comparison with the area of the interface.

From the electrical theory of adsorption previously mentioned Iliin⁴⁸ has obtained for the heat of adsorption the equation

$$H = \frac{E_o^2}{8\pi} \left(\frac{\epsilon - 1}{\epsilon} \right)$$

where E_o is the tension of the electrical field in vacuo, and ϵ is the dielectric constant of the adsorbed gas. This equation is in good agreement with the experimental results of Homfray and Titoff. The same equation has been derived by Tarasoff,¹⁰² who has also shown that $H\nu^2$ is a constant for a given adsorbent, where ν is the ionisation potential of the adsorbed gas.

Note on the Formulation of Adsorption Laws

For a theoretical investigation of the laws of adsorption two general methods are available; first, a development from the fundamental laws of thermodynamics, and second, a discussion of the kinetics of the adsorption process. Thermodynamic treatment has the great advantage that it does not

require a knowledge of the intimate mechanism of the process, and in particular it involves no assumptions with regard to molecular attraction. On the other hand no relation for the rate of adsorption can be obtained from thermodynamics alone. Kinetic treatment permits of the deduction of a rate of adsorption equation, but when an attempt is made to allow for the interaction of molecules the mathematics becomes so involved as to be impossible of solution.

The conditions obtaining in a solution are so complicated that it will probably be of little avail attempting to postulate any theory of adsorption from solution until our knowledge of the laws underlying adsorption from the gaseous phase is much more complete. It would seem that an adequate theory of gaseous adsorption should distinguish between a gas above and below its critical temperature. For the former there is no possibility of condensation to liquid, so that the adsorption layer would consist of gas, probably compressed, and would vary in thickness according to the pressure. For such conditions thermodynamic treatment has been successfully used, as witness the remarkable agreement between Briggs' experimental data and Williams' equation for the isotherm.

For a gas below the critical temperature a layer of gas would be expected at low pressures, but as the pressure is increased condensation might occur, with the formation of a liquid film. If the adsorbent were porous a simultaneous condensation would take place in the pores,⁶⁰ obeying, probably, quite other laws. Anderson, Zsigmondy, Fisher, Trouton, and Gustaver believe that this condensation takes place according to Kelvin's equation

$$r = \frac{2\sigma D_v}{D_l \text{Plog } P/p}$$

where r is the radius of the liquid meniscus,

D_v is the vapour density at pressure P ,

and D_l is the liquid density.

Wilson¹¹⁵ considers that this equation is only applicable to pores of radius greater than 5×10^{-8} centimetres. It may well be, however, that the breakdown for very small pores is due not so much to an imperfection in the equation as to the insertion of the wrong value of σ in it, since it is not permissible to assume that the surface tension of such very thin films is identical with that of the liquid in bulk.

Most of the evidence with regard to an *adsorbed* liquid film (as distinct from a column of liquid in a pore) tends to show that it is very thin. Thus Katz^{45, 46} has shown from the equation $F = RT \log p/P$, where F is the molecular attraction, that the force of attraction diminishes rapidly with increase of thickness, whilst Hatschek³⁸ by means of the Einstein-Hatschek viscosity equation has shown that the thickness of the adsorbed film on the spheres of a suspension in sodium chloride solutions is of the order 8×10^{-8} centimetres, which is about twice the diameter of a water molecule. On the other hand, reference must be made to some recent work of Hardy,³⁴ which shows that a surface may exert a specific effect through a layer of liquid probably some hundreds of molecules thick. For a reconciliation of these divergent views we must look to the future.

ADSORPTION AND HEAT OF ADSORPTION OF AMMONIA GAS ON METALLIC CATALYSTS*

BY WALTER A. DEW AND HUGH S. TAYLOR

In order that a more extensive knowledge might be acquired of the relationship existing between heat of activation, adsorption, heats of adsorption and catalytic activity, measurements of the specific adsorption and the heats of adsorption of ammonia gas on copper, nickel and iron catalysts have been made. These determinations combined in one operation three lines of investigation which had been previously carried out in this laboratory. Adsorption measurements have been made such as those of Taylor and Burns¹ while isotherms for ammonia and hydrogen corresponding to the investigations of Gauger and Taylor² and integral and differential heats of adsorption were measured in the same manner as did Beebe and Taylor.³

Although it is known that substances which possess a great adsorbing power are not necessarily the best catalysts,⁴ yet much emphasis has been placed upon the determination of specific adsorption of catalytic agents as a criterion for their activity in certain reactions and there seems to exist an intimate relationship between the specific adsorption and catalytic activity.⁵ Assuming some relationship to exist between the adsorbent and the adsorbed gas it was thought that adsorption measurements upon various catalysts which cause the decomposition of ammonia might reveal some data of fundamental nature concerning the reaction,

That iron at elevated temperatures causes this decomposition to take place was first investigated by Ramsay and Young⁶ and, subsequently, more thoroughly by Beilby and Henderson⁷ who, in addition, studied the action of ammonia on nickel, copper, silver, gold, and platinum, and various other metals and alloys at temperatures lower than their melting points. The latter authors concluded that the decomposition of ammonia is due to a nitride formation occurring when excess ammonia is present.

Although no measurements have been made of the specific adsorption of ammonia gas for any of the metals previously mentioned it has been found by Taylor and Burns⁸ that iron adsorbs hydrogen gas to a certain extent and that nitrogen gas is not measurably adsorbed. Nickel and copper have been in-

vestigated more thoroughly and the heats of adsorption of hydrogen determined by Beebe and Taylor¹ under various conditions. These metals also show no measurable adsorptive capacity toward nitrogen. In addition, a few adsorption measurements were made on a supported sodium catalyst. Catalysts from several groups of metals were thus represented. Some work previously carried out in this laboratory by Dr. A. F. Benton on the adsorption of ammonia gas by a 50-50 mixture of iron-molybdenum has been incorporated also with these measurements.

Of the metals examined, sodium is known to react with ammonia at 300°-400°C. to produce sodamide² according to the equation

Since it is a very reactive metal it might be expected that irreversible adsorption alone would be observed. At the temperature at which the determination was made, however, reversible adsorption occurred. The remaining metals would be expected to show reversible adsorptions and this was found to be the case.

The relationship existing between the heat of activation and heat of adsorption has been clearly stated by C. N. Hinshelwood³ as follows:

$$E_o = E_t + \lambda' - \lambda$$

where

E_o = the observed heat of activation

E_t = the true heat of activation

λ' = the heat of desorption

λ = the heat of adsorption

and the value for λ' for hydrogen on catalytic nickel has been measured by Beebe and Taylor⁴ and also by Foresti⁵ and more recently by Fryling⁶ who extended the work to promoted nickel catalysts at low pressures. Beebe and Taylor also measured the heat of adsorption of hydrogen on copper.

Experimental

METHODS OF MEASUREMENT:—In carrying out the adsorption measurements the apparatus employed was entirely similar to that used and described by Pease and the temperatures employed were 0°, 110°, 218°, 305° and 444.6°C. which were attained by the use of ice and water, boiling toluene, naphthalene, acetanilide and sulphur respectively. The temperature regulation in the case of the determinations on iron-molybdenum was achieved by water at 25°C. and 100°C. and by an electrically heated air bath at the higher temperatures. Evacuation in this latter case was accomplished at 500°C.

Evacuation at room temperature was employed for sodium, and a temperature of 218° was commonly used for copper, nickel and iron except where determinations were carried out at higher temperatures in which case the tube was evacuated at the higher temperature.

Nitrogen was used as the reference gas by which the free space of the bulb was obtained, since it was found by Taylor and Burns to be unadsorbed.

When heat of adsorption measurements were made a catalyst tube exactly similar to the one employed by Beebe and Taylor, with an estimated capacity of about 50 cc. when empty, was substituted for the catalyst tube previously used. Catalyst transfer from a separate reduction tube was accomplished in an atmosphere of inert gas. The heating coil used was made of platinum-palladium wire of 0.10 mm. diameter and 44.3 cm. in length and had a resistance of 10.005 ohms. The coil was insulated to prevent short circuiting as described by Beebe and Taylor. The leads, welded to the heating coil, were made of stout wire as short as possible and terminated in mercury cups by means of which connection was made to the calibration apparatus. Calibration was carried out exactly as described by Beebe and Taylor, the 10 ohms heating coil being employed. Care was exercised to keep the leads and mercury cups well below the surface of the ice bath to prevent any loss of heat by conduction.

For evacuation, the catalyst tube was heated by means of an air bath, the de Khotinsky joint being protected by a small lead tube wrapped about it several times, through which tube water circulated. In the case of copper, evacuation was carried out at 200°C., but 300°C. was employed for both nickel and iron. A Dewar flask filled with water and cracked ice was placed about the catalyst tube after evacuation was complete and all determinations of heats of adsorption were made at 0°C.

Nitrogen was employed as a reference gas, since it was found by Beebe and Taylor to be unadsorbed and consequently a suitable gas by which thermal effects, due to compression of the gas entering the calorimeter and to cooling from room temperature, could be observed. Calibration measurements were carried out, however, with the catalyst chamber filled with ammonia gas. It was found necessary also to introduce a correction factor for the effects noted above due to the fact that nitrogen is a diatomic gas and ammonia is a tetratomic gas. These corrections will be fully considered later.

CATALYST PREPARATION:—Sodium was prepared by distilling the metal in vacuo and condensing it upon glass beads in the reaction tube. This was accomplished by drawing the tube out into two bulbs quite similar to an old-fashioned hour glass. Into the lower one was introduced a weighed piece of sodium, and the upper was filled with glass beads. The upper bulb was sealed to a capillary tube which was attached to the apparatus. A Toepler pump was used to evacuate the system as it was heated. Distillation was carried out at 400-450°C. and a silvery mirror of sodium was deposited on the glass beads. The tube containing the catalyst was then sealed off and the weight of the sodium which had distilled was obtained.

• *Copper 2* was prepared from Kahlbaum's "brown label" copper oxide ground to granules of about 2 mm. in size. Reduction was carried out at 145-150°C. for a period of six days in a stream of pure dry hydrogen. The end point of the reduction was indicated when no increase was observed in the

weight of a calcium chloride tube through which the effluent hydrogen was allowed to pass for an hour.

Copper A was prepared in the same manner as Copper 2 except that the temperature of reduction was maintained at 140-145°C. for a period of twenty-two days. At the end of that time the reduction was still producing 0.6 mg. of water vapor per hour.

Nickel 8 was prepared by igniting the pure nitrate in a casserole over a small flame, transferring this material to the reduction tube, calcining at 300°C. and reducing in a stream of hydrogen as described by Gauger and Taylro for the unsupported catalyst which they used.

Nickel A was prepared in the same manner as Nickel 8 the reduction temperature being maintained at 285-300°C. Reduction was slow at that temperature, for at the end of fifty days 0.4 mgm. of water vapor was being formed per hour. Noticeable contraction of the mass was observed at the end of the reduction period.

Iron 1 was prepared by dissolving pure soft iron turnings in nitric acid. The resulting nitrate solution was filtered, evaporated to dryness and ignited slowly on a sand bath. Reduction was carried out in a stream of dry electrolytic hydrogen at a temperature of about 600°C. for a period of sixteen days.

Iron A was prepared exactly as Iron 1 except that the reduction temperature was maintained at 440-460°C. At the end of thirty days no formation of water was observed and reduction was considered complete.

Iron-molybdenum was prepared by dissolving 113 g. of soft iron in equal volumes of concentrated nitric acid and water, adding to this solution 227 g. of ammonium molybdate dissolved in water. The combined solution was evaporated to dryness, stirring constantly toward the end. It was then ignited on a sand bath to drive off excess nitric acid. Reduction was carried out in hydrogen at 445° for 20 hours, at 500° for 10 hours, and at 530° for 26 hours. At the end of this time reduction was not absolutely complete, water being formed at the rate of 18 mg. per hour.

PREPARATION OF GASES:—Nitrogen was obtained by passing tank nitrogen through a purifier, containing a solution of ammoniacal cuprous carbonate, to remove oxygen, washing with sulphuric acid, then passing over hot copper to remove traces of oxygen, and drying by passing through calcium chloride.

Hydrogen was prepared electrolytically as described by Pease.¹

Ammonia was prepared by gently warming concentrated aqua ammonia in a large flask and passing the gas through drying towers filled with soda lime and potassium hydroxide. Before introducing the gas into the measuring burette it was tested for its solubility in water, portions of the gas being taken which were completely soluble in water.

Experimental Results .

ADSORPTION DATA:—In Table I are the values obtained for the adsorption of hydrogen and ammonia on the various catalysts at the several temperatures mentioned. The specific adsorption or the cc. of gas adsorbed by one gram of

¹ Pease: J. Am. Chem. Soc., 45, 1196 (1923).

metal is noted instead of the volume adsorbed by one volume of catalyst. In order to compare these values, therefore, with those given by other observers¹ it is only necessary to multiply the value of the specific adsorption by the density of the metal catalyst to obtain the volume adsorbed by one volume of the metal. These values were checked so that all results were reproducible with the sample examined.

TABLE I

¹ Taylor and Burns: J. Am. Chem. Soc., 43, 1277 (1921); Gauger and Taylor: 45, 923 (1923); Hempel and Thiele: Z. anorg. Chem., 11, 93 (1896); Mayer and Altmayer: Ber., 41, 3062 (1908); Troost and Hautefeuille: Compt. rend., 80, 788 (1875).

COPPER. Upon comparison of the values obtained for the adsorption of hydrogen by copper (namely 1.381 vols. per 1 vol. of copper) with the values obtained by Taylor and Burns (less than 0.05 vols. per vol. of copper) it is seen that the amount adsorbed is some 200 times as great at 110° and is more than 5 times as great as that observed by Pease who obtained 0.232 vol. per vol. of copper but is about one-third of that obtained by Beebe and Taylor, who found 3.8 vols. per vol. of copper.

The comparatively large adsorption of hydrogen observed by copper is probably due to the fact that the temperature of reduction was low.

The value obtained for the specific adsorption of ammonia on copper is large compared to the hydrogen value showing that the sample investigated possessed good adsorptive power for ammonia, the value being readily measurable at all temperatures employed. In no case was there any indication of decomposition of the ammonia by the copper at the three temperatures employed as shown by the observation that the ammonia gas when pumped off was completely soluble in water.

NICKEL. Nickel was observed to adsorb ammonia very strongly, giving a value which is nearly twice as large as that obtained for copper at 0°. At 213°, however, the initial volume adsorbed began to decrease slowly, indicating plainly that decomposition of the ammonia was taking place.* This decrease was not noticeable in the first five minutes, after which time it fell away until a constant value was reached. The gas which was pumped off the catalyst was tested qualitatively for hydrogen which was found to be present.

At 305° the amount of decomposition of ammonia was slight and took several minutes before it became measurable, which was probably due to the small adsorption of the ammonia by the nickel.

IRON. The values obtained for the adsorption of hydrogen were found to be small, checking closely with those obtained by Taylor and Burns.¹

Adsorption of ammonia was much larger than that of hydrogen but not so large as might be expected were total adsorptive capacity the only criterion of activity. This may be attributed to the high temperature at which the iron was reduced and, as will be indicated later, this point of view is substantiated for Iron A on which heat of adsorption measurements were made. This sample showed adsorptions that were nearly as large as Nickel 8. These measurements indicate by contrast the importance of maintaining low temperatures in the preparation of unsupported catalytic materials if they are to have a high adsorptive capacity.

In making the measurements no decomposition of ammonia was observed at any temperature until 444.6°C. was reached. Considerable decomposition of the gas took place at this temperature as was indicated by collecting 9.8 c.c. of the desorbed gas of which only 4.1 cc. was soluble in water.

* Note:—It should be noted here that the initial value was taken as that of true adsorption instead of a value taken when the reading of the burette became constant as was the case at lower temperatures. In taking the initial value no doubt some error is involved since it is not known how rapidly the ammonia is decomposed at those temperatures.

¹ Taylor and Burns: *J. Am. Chem. Soc.*, 43, 1280 (1921).

Adsorption Isotherm of NH₃ on Copper at 218°:—Since copper was found not to decompose ammonia at 218° it was decided to obtain an isotherm curve which would indicate the nature of the ammonia adsorption at 218°. The following diagram, Fig. 1, indicates very clearly the relationships which are found to exist between the pressure and the volume adsorbed. It will be observed that there is strong adsorption at low pressures. At 400 mm. the adsorption has reached 3.4 cc., whilst an additional 400 mm. pressure results only in the adsorption of a further 0.6 cc. This indicates approaching saturation of the surface.

FIG. 1

Isotherms for NH₃ on Nickel at 110° and 0°C:—The accompanying curves, Figs. 2 and 3 indicate the variation of the adsorption of ammonia gas with pressure at the two temperatures. It may be observed that the NH₃ curve on nickel at 110°C. is very similar to that obtained on copper which has just been described. At 0°C., however, the adsorption of ammonia at the lower pressures is quite marked but there is little evidence of approaching saturation even at the highest pressures studied.

IRON-MOLYBDENUM. The results of the measurements of adsorption on this catalyst sample may be briefly summarized in a table.

TABLE II

Catalyst	wt. in grams	Gas	cc. Gas required to fill bulb at N. T. P.		Specific Adsorption	
			25°	100°	25°	100°
Iron Molybdenum	125	H ₂	69.30	55.2	0.0032	0.0
		NH ₃	357.4	—	2.30	—

Benton says: "No solution of hydrogen or chemical reaction occurred at 25° since equilibrium was always quickly reached and the curves coincide for introducing and withdrawing the gas, all the hydrogen being recovered. The same is true at 100° except that 0.37 cc. of hydrogen were not recovered and therefore presumably reacted with the unreduced oxide.

FIG. 2

"If any hydrogen is adsorbed at 25° or 100° it must be roughly proportional to the pressure. If it be assumed, however, that no hydrogen is adsorbed at 100° the free space in the bulb is $55.2 \times \frac{372.2}{273} = 75.2$ cc. and the volume of gas required to fill this space at 25° would be 68.9 cc. Actually, however, 69.3 cc. of hydrogen at 25° were needed. Hence the minimum adsorption of hydrogen at 25° was 0.40 cc. which is the order of magnitude obtained by Taylor and Burns for hydrogen on iron.

"In any case, since the volume adsorbed cannot possibly vary inversely as the absolute temperature, these calculations show that Fe-Mo adsorbs scarcely any hydrogen at 25° and 100° and, therefore, hydrogen determinations can be used to determine the free space in the bulb, especially as the ammonia adsorptions are large." The isotherm given, Fig. 4, indicates that the amount of ammonia adsorbed at low pressures is very large.

Heats of Adsorption.—A slight deviation from the method used by Beebe and Taylor was necessitated by the fact that nitrogen, a diatomic gas, was

employed to determine the heat effects previously mentioned, whereas ammonia is a tetratomic gas. This can probably be illustrated best by an example or typical calculation as in the case of

NICKEL A. Determinations of Free Space and Heat Effects employing the average of Runs 1 and 2.

FIG. 3

3rd " ".....		0.002	
<hr/>		<hr/>	

True Temperature Rise.....0.058

Average Volume N₂ Introduced.....39.93 cc. N. T. P.

Mol. Heat of NH₃ = 0.5202 × 17 = 8.84

" " " N₂ = 0.2438 × 28 = 6.82

Amount of heat N₂ would liberate in cooling from 21.1°C. to 0° is given thus:

$$\text{N}_2 \text{ heat capacity} = \frac{39.93}{22,400} \times \frac{6.82}{13.75} \times 21.10^\circ = 0.019^\circ.$$

where 13.75 calories = Heat capacity of Calorimeter.

Total Temperature Rise = 0.058°

N₂ heat capacity = 0.019.

Hence, by subtraction, the heat effect due to compression = 0.039°.

To find the NH_3 equivalent of the nitrogen value for heat capacity of the gas, we have, $0.019^\circ \times \frac{8.84}{6.82} = \text{NH}_3$ equivalent, or 0.024° , due to heat capacity of the ammonia. Hence the total effect due to introducing 39.93 ccs. NH_3 is $0.024 + 0.039 = 0.063^\circ\text{C}$. The remaining calculations are similar to those of Beebe and Taylor.

FIG. 4

Copper.—This catalyst was prepared as previously described in order to reproduce the sample upon which adsorption measurements alone were made. It is of interest to note the extent of this reproducibility. The following table reveals that the average volume of ammonia taken up by the sample was 17.37 cc. which gives a specific adsorption of 0.4958 cc. per gram for copper A as compared with 0.4577 cc. per gram for copper 2. This shows a reproducibility of about 6 per cent.

The results obtained for the heat of adsorption on copper may be summarized most conveniently in two tables, the first showing determinations of the integral heats of adsorption and the second showing heats of adsorption at various partial pressures.

TABLE III

Integral Heat of Adsorption
Copper A. Weight 35.03 grams

Determination	c.c. adsorbed (0, 760)	Temp. Rise	
1	17.50	0.455	7,711
2	17.25	0.449	7,720

The heat capacity of the calorimeter was found to be 13.24 calories.

TABLE IV

Differential Heat of Adsorption. (Q at Partial Pressure).

Determination	Pressure in m.m.	cc. adsorbed (0, 760)	Temp. Rise	λ

3	155	7.00	0.218	9,236
4	192	9.13	0.266	8,663

Nickel A.:—The catalyst used here was prepared in order that it might be as nearly as possible of the same activity as the first sample on which adsorption measurements were made. Though greatest care was exercised the latter catalyst was about 14 per cent less active in ammonia adsorption than the first. One run was made to determine the integral heat of adsorption of hydrogen on this catalyst. A value of 14,960 calories was obtained which checks very well with those obtained by Beebe and Taylor.

The results of the integral heat of adsorption measurements of ammonia on nickel may be tabulated as follows:

TABLE V

Integral Heat of Adsorption of Ammonia on Nickel

Determination	c.c. adsorbed (0, 760)	Temperature Rise	λ
1	21.19	0.772	11,220
2	21.00	0.789	11,570

The heat capacity of the catalyst and calorimeter was 13.75 calories.

TABLE VI

Differential Heats of Adsorption on Nickel A

Deter- mination	Initial Pressure	Final Pressure	c.c. Vol. gas Adsorbed (0, 760)	T - T°	λ
1	0	183.5	11.90	0.445	11,520
2	0	198	13.94	0.446	9,854
3	0	210	11.79	0.412	10,760
3A	210	758	6.82	0.170	7,677
4	0	141	10.03	0.360	11,060

6C	511.5	756	2.54	0.058	7,033

T is the highest temperature observed plus corrections.

T₀ is the initial temperature.

It will be observed that the heat of adsorption of ammonia at low pressures is about 11,300 calories and gradually decreases to about 7,000 calories as the pressure increases.

Iron A. In order that a catalyst of greater adsorptive capacity might be obtained, the reduction temperature was maintained as low as possible. The sample examined weighed 49.35 grams and showed a specific adsorption of about 0.5 cc. per gram which is about three times as large as that of iron 1 at 0°C. It is approximately thirty per cent less, however, than the specific adsorption of Nickel A at 0°C. The heat capacity of the catalyst and calorimeter in these measurements was 17.98 calories. No determinations were made of the integral heat of adsorption. Table VII gives the differential heats of adsorption.

FIG. 5

TABLE VII
Differential Heats of Adsorption in Iron A

Deter- mination	Initial Pressure	Final Pressure	cc. Vol. gas adsorbed (0, 760)	T - T ₀	λ
1	0	16	8.05	0.320	16,010
1A	16	97.5	5.61	0.152	10,910
1B	97.5	368	6.84	0.155	9,127
1C	368	756	5.61	0.113	8,113
2	0	16	7.56	0.292	15,580
2A	16	102.5	5.99	0.142	9,548
2B	102.5	368	5.02	0.122	9,788
2C	368	756	4.43	0.088	8,008

At low pressures it will be seen that the heat of adsorption of ammonia on iron is about 16,000 calories, a value much larger than that obtained in the case of nickel.

Employing the value of 38.22 cc. for free space obtained by using nitrogen it is possible to obtain an isotherm curve (Fig. 5) for ammonia on iron at 0°C. It may be noticed that the curve obtained is quite similar to the isotherm of ammonia on nickel at the same temperature.

Discussion of Results

All the catalysts studied have been shown to possess adsorptive capacity for ammonia at the temperatures studied and the adsorption has been shown to be reversible in the lower range of temperatures employed. At the higher temperatures decomposition of ammonia occurs.

From the known reactivity of ammonia with sodium to yield sodamide¹ and from the presence of nitrogen in samples of nickel and iron which have been used to decompose ammonia, we may conclude that the ammonia is attached to the metal surface² by a metal-nitrogen linkage. At low temperatures the ammonia may be removed intact. As the temperature is raised, however, internal rearrangements in the adsorbed ammonia molecule may occur. In the case of sodium, this leads to a definite compound, NaNH_2 , with elimination of one atom of hydrogen from each ammonia molecule. In the case of the other metals such compounds are not identifiable but it is found that the hydrogen comes off in such cases prior to the nitrogen, leaving the metal charged with this latter, not however in definite stoichiometric proportions.

Assuming that the whole surface is not uniformly active and that it is the fraction of the surface having the strongest adsorptive capacity which is the most active catalytically, it is of interest to note that the heats of adsorption at very low partial pressures stand in the order (1) iron, 16,000 calories; (2) nickel, 11,300 calories; (3) copper, 8,700 calories. It is these values which are to be inserted for λ in the expression

$$E_0 = E_t + \lambda' - \lambda$$

previously given. This would indicate that the apparent heat of activation, E_0 , would be most markedly affected by the heat of adsorption in the case of iron, least in the case of copper. There is, however, another point of view in this respect. The higher heat of adsorption of ammonia on iron means that it is possible to raise an adsorbed molecule to a much higher temperature on an active iron spot than on an active copper spot. There is thus offered a greater probability of interaction between the metal atom and the ammonia molecule in the case of iron than in the case of copper. It is possible that the higher activity of iron as a catalyst for ammonia decomposition is to be associated with this observation. Expressed otherwise, there is the possibility of inelastic collisions between impinging ammonia molecules and the metal surface at much higher temperatures in the case of iron than in the case of copper, which is equivalent to saying that the 'active mass' of ammonia is greatest in contact with iron at the temperature in question.

Summary

(1) Values for the specific adsorption of ammonia and hydrogen gases were determined for sodium, copper, nickel, iron, and a 50-50 mixture of iron molybdenum at various temperatures.

¹ Titherley: J. Chem. Soc., 65, 504 (1894).

² Beilby and Henderson: J. Chem. Soc., 79, 1250 (1901); Fowler: 79, 288 (1901); White and Kirschbaum: J. Am. Chem. Soc., 28, 1347 (1906).

(2) Adsorption isotherm curves were determined for ammonia on copper at 218° , on nickel at 110° and 0° , on iron molybdenum at 25° and on iron at 0° .

(3) Integral heats of adsorption for ammonia gas at 0°C . on copper, and nickel have been determined.

(4) Differential heats of adsorption for ammonia gas at 0°C . on copper, nickel, and iron have been tabulated.

(5) The effect of temperature on the preparation of unsupported active catalyst samples has been emphasized.

(6) An apparent relationship between heat of adsorption and catalytic activity has been presented in the case of the reaction $2\text{NH}_3 = \text{N}_2 + 3\text{H}_2$.

THE NEUTRAL SALT EFFECT*

BY L. E. BOWE

Historical

In 1888 Spohr¹ and in 1889 Arrhenius², in experimenting on the catalysis of the hydrolysis of sugar and ethyl acetate, found that the addition of some neutral salts increased the rate of inversion of cane sugar and the hydrolysis of ethyl acetate in the presence of a constant amount of acid. They found that the more dilute the acid, the greater was the effect of the added salt. Arrhenius³ offered several explanations for this effect, some of which still find favor today. He attributed the increase in velocity to one or more of three causes.

1. The increase in the ionization of the acid.
2. The increased ionization of the water.
3. The shift in the equilibrium "inactive \rightleftharpoons active" molecules, to the right on the addition of neutral salts.

Euler⁴, working on the same problem, attributes the "salt effect" to the fact that water reacts through its ions and that salts affect reactions by changing the dissociation constant of the water. This is still believed by some to be one of the factors in this complicated problem. Euler's theory is merely an enlargement of that of Arrhenius.

Since that time considerable work has been done on this question and several theories have been suggested, some of which will be enumerated here. Hardly any one of them agrees with another and which is the correct theory is still a much argued question.

Lamble and Lewis⁵ seem to have disproven Arrhenius' theory of "active" and "inactive" molecules, assuming there are such, for we have no proof of it. According to Arrhenius the large temperature coefficient of many reactions is due to the changing of "inactive" into "active" molecules. A catalyst is supposed to act in the same way, causing a shift in this equilibrium. By using a large amount of catalyst the majority of "inactive" molecules would be changed into "active" molecules and then the temperature coefficient should not be so large. But Lamble and Lewis find that the addition of neutral salts causes no change in the temperature coefficient. They offer the suggestion that catalysis is a "radiation" phenomenon. According to this, reactions are catalyzed by the absorption of radiation which the hydrogen ion emits due to its vibration to and fro between two neighboring molecules.

Acree¹, who has done considerable work on catalysis says it may be that the changes assumed by Euler play a minor part. He suggests that "reactive" and "less reactive" double salts are formed between the added salt and the reacting substance. These accordingly speed up or slow up the reaction. He also states that changes in solvation, viscosity, vapor pressure, or osmotic pressure also play a part. According to Acree neutral salts change the thermodynamic potential because this depends not only on the substances themselves but also on the surrounding field.

Wilson² believes that removal of the solvent by hydration of the salt accounts for the rise in the hydrogen ion concentration. Manning³ attributes the salt effect to at least two causes acting together. One, which he calls the *true* salt action, is a change brought about by the formation of a new molecular species. $HA + BC \rightarrow HC + BA$. This is accompanied by a readjustment of the concentration of the ions present. The other effect is hydration. He finds that the non-electrolytes, glucose and sucrose, do not increase the rate of hydrolysis of ethyl formate to any appreciable extent. He says: "Therefore . . . it may be concluded that the rate of reaction is independent of changes in concentration of the water. In other words, hydration of the solute does not affect k ." He also says that changes in viscosity have little effect and suggests that the acceleration is due to actual changes in the concentration of hydrogen ions in solution. Mannitol⁴, a neutral non-electrolyte, and even sucrose itself, will increase the hydrolysis of sucrose.

Taylor⁵ says that undissociated molecules of the acid have a catalyzing effect. Åkerlöf⁶ believes that the theory of the undissociated molecule having catalytic activity is not correct. He says that the salt molecule does not possess any activity of its own, but is merely the *cause* of the change in the activity of the catalyst. The salt effects a change in the water envelopes surrounding the hydrogen ions. The concentration of the hydrogen ions remains the same while their activity undergoes a change.

Dhar⁷ found that the action of neutral salts is highly specific, some accelerating, some retarding the speed of a reaction. Their presence does not alter either the order of the reactions or their temperature coefficients. Rice and Lemkin⁸ found that the temperature coefficient was lowered in some cases (by sulphates).

Stieglitz⁹ favors the view of Arrhenius that the increase is due to the increased ionization and activity of water. He also says: "The neutral salt effect is due to the fact that we are working with mixed solvents, in which

ionization, velocities, etc., cannot be expected to be the same as in a pure solvent."

This last suggestion that Stieglitz makes approaches closely the theory which Professor Bancroft suggests and which will be mentioned below. This work was undertaken with the view of testing this theory.

Experimental

The theory that liquid water is a polymerized liquid has been fairly well substantiated¹. According to this theory liquid water is assumed to be mainly "dihydrol", $(\text{H}_2\text{O})_2$. It also assumes that there are other polymers present and that these different forms are all in equilibrium. For example,

When neutral salts are added to water, they probably cause a shift in this equilibrium², giving, at least in some cases, more molecules of "monohydrol", (H_2O) . If this is the case we shall have a *different* solvent in which concentrations, reaction velocities, ionization, etc., will be different from those in the original solvent.

With this theory in mind the hydrogen ion concentration in 1/10 normal hydrochloric acid solutions containing one, two, three, and four normal NaCl, NaBr and NaI, was measured with the hydrogen electrode. The effect of these salts on the rates of hydrolysis of sucrose and ethyl acetate was also determined.

Electrometric Measurement of Hydrogen Ion Concentration

For these experiments and all of the following ones, the hydrochloric acid solution was made by redistilling a 20% solution of "C.P." HCl, collecting the middle fraction of the distillate. This was then diluted and standardized carefully. The sodium bromide and sodium chloride were recrystallized and thoroughly dried. The sodium iodide used was Kahlbaum's C.P.

Such a quantity of the salt used was introduced into a 50 cc. measuring flask, that when dissolved and diluted to 50 cc. it would give the normality of the salt desired. A quantity of the standardized HCl was added, from a calibrated burette, such that when diluted to 50 cc. it would give 0.1 N HCl. For example, 2.923 gm. of NaCl and 28.62 cc. of 0.17472 N HCl were introduced into the measuring flask and then diluted to 50 cc. This gave a solution one normal with respect to NaCl and 0.1 N with respect to HCl. This solution was then introduced into the hydrogen electrode half of a cell, the other half being a saturated KCl—calomel electrode. The two units were connected in the usual manner³ by a salt bridge of saturated KCl solution. The E.M.F. of this cell was measured by means of a Leeds and Northrup potentiometer, recording the temperature at which the experiment was made. The hydrogen for the electrode was run from a tank through a hot electric coil to remove the oxygen, and then through a wash-bottle containing dis-

³ Hildebrand: J. Am. Chem. Soc., 35, 847 (1913).

tilled water. This saturated the hydrogen with water vapor and thus prevented it from changing the concentration of the solution in the cell to any appreciable extent. The cell was always allowed to come to equilibrium before the final measurement was taken. No reading was taken as final until the E. M. F. became constant. The hydrogen electrode was kept in distilled water while not in use, being rinsed off each time with the solution in which it was to be run.

Having measured the E.M.F. of this cell, the apparent hydrogen ion concentration was calculated by means of the following equation:

$$E_{(\text{cell})} = \frac{RT}{nF} \log \frac{1}{(H')} + \text{(value of sat. KCl-calomel electrode against the normal hydrogen electrode at the temperature of the experiment).}$$

where RT/nF was substituted by its value at that temperature along with the conversion factor to Briggsian logarithms.

The E.M.F. of a cell with 0.1 N HCl alone, as the solution in the H electrode, was measured several times, and a constant value was obtained. The salt solutions of 0.1 N HCl were then substituted for the 0.1 N HCl and the E.M.F. of each solution against the calomel measured.

0	.3080	.096	—
1	.2900	.192	100
2	.2842	.241	152
3	.2672	.472	391
4	.2476	1.020	1062

The liberation of free iodine in the iodide solutions made the results for these somewhat inaccurate. The measurement of the E.M.F. of these solutions was made as soon as possible after making up the solution. In the last column of Table I is given the ratio:

$$\frac{\text{apparent } (H') - \text{original } (H')}{\text{original } (H')}$$

It can be seen that the apparent hydrogen ion concentration is increased as much as 1000 percent in the case of the four normal sodium iodide solution. It is not likely that the actual hydrogen ion concentration is increased this much. It will now be shown how this increase may be accounted for by the theory mentioned above.

The equation for calculating the hydrogen ion concentration by this method is derived in the following manner:

Nernst's equation for a single electrode potential, Π is $\Pi = RT/NF \log P/p$ where P is the electrolytic solution pressure of the metal (or in this case hydrogen) and p is the osmotic pressure of the hydrogen ions.

If we have two hydrogen electrodes dipping into solutions of different concentrations of H^+ ions, and eliminate or correct for the difference of potential between the two solutions, the expression for the E.M.F. of this cell is

$$(1) \quad E_{\text{Corr.}} = \pi_1 - \pi_2 = \frac{RT}{nF} \log \frac{P_1}{p_1} - \frac{RT}{nF} \log \frac{P_2}{p_2}$$

Then, since we have the same metal (H_2) dipping into two different concentrations of its ions, $P_1 = P_2$ and equation (1) becomes

$$(2) \quad E_{\text{Corr.}} = \frac{RT}{nF} \log \frac{p_2}{p_1}$$

In so far as the osmotic pressure is proportional to the concentration we may substitute the ion concentrations c_1 and c_2 for p_1 and p_2 . Then

$$(3) \quad E_{\text{Corr.}} = \frac{RT}{nF} \log \frac{c_2}{c_1}$$

Now if the solution c_2 is made one normal with respect to hydrogen ions or $c_2 = 1$, equation (3) becomes

$$(4) \quad E = (RT/nF) \log 1/c_1$$

where c_1 is the solution of unknown concentration of hydrogen ions. Knowing the E.M.F. of this cell c_1 could be calculated. However, a hydrogen electrode with a solution one normal with respect to hydrogen ions is difficult to produce, so a saturated calomel electrode is used in place of the normal hydrogen electrode. Since this is about 0.25 volts more positive than the hydrogen electrode, the value of the E.M.F. of this cell is 0.25 more than it would be with the normal hydrogen electrode and equation (4) becomes

$$E = (RT/nF) \log 1/c_1 + 0.25$$

The 0.25 is, of course, substituted by the value the sat. calomel would have against a normal hydrogen electrode at the temperature of the experiment.

It was assumed, in deriving equation (2) that the electrolytic solution pressure (P) of hydrogen was the same in all solutions of its ions. *However*, according to the theory of the shift in the water equilibrium, upon the addition of neutral salts, this is *not* true. We have here a different solvent in which the electrolytic solution pressure is not the same as in water in which neutral salts are not present. Therefore, the equation used to calculate the hydrogen ion concentration would not hold if the electrolytic solution pressure changes. Consequently, the values obtained are not the *true* values of the hydrogen ion concentration, but only the *apparent* hydrogen ion concentrations.

It was thought that the neutral salts, NaCl, NaBr and NaI would affect the equilibrium in the order of Hofmeister's series, i.e. $I > Br > Cl$. This was found to be true. The bromide gave a greater apparent hydrogen ion concentration than the chloride, and the iodide produced a greater effect than the bromide. This does not agree with the work of Harned¹ who finds that bromides and chlorides have about the same effect on the hydrogen electrode potential. V. A. Arkadiev², however, obtained the same relative results that the present work indicates.

Hydrogen Ion Concentration as measured by the Reaction Velocity of Sucrose Inversion.

Since sugar inversion is catalyzed by acid, the rate of inversion can be used as a measure of the hydrogen ion concentration. Experiments were conducted on the increase in the rate of inversion upon addition of the neutral salts used above.

The sugar used in these experiments was of a pure commercial brand that had been dried for two or three days at about 60°C. It was kept in a desiccator over pure concentrated sulphuric acid. The rate of inversion was followed by a Bausch and Lomb saccharimeter. The "normal" solution for this instrument called for 26 gm. sugar per 100 cc. of solution. In these experiments, 6.5 gm. of cane sugar was accurately weighed out each time. This, dissolved and diluted to 50 cc., gave a "half-normal" solution which read "50" on the saccharimeter. The salts and acid were added as before with the exception that the sugar and the salt in the measuring flask were dissolved as much as possible in about 25 cc. of distilled water allowing space enough for the acid to be added. When the acid had been added and the whole diluted to 50 cc. the time was noted. The solution was then placed in a polariscope tube, 20 cm. in length, being careful not to allow any air to remain in the tube when it was closed. The tube was suspended in a thermostat which was regulated at 25°C. $\pm .05^\circ$. Readings were taken on the saccharimeter at different intervals of time and recorded after correcting for the "zero" reading of the instrument. This "zero" reading was taken before and after each reading. The reaction was allowed to continue until a constant reading was obtained. This was taken as the final reading after complete inversion had taken place.

¹ J. Am. Chem. Soc., 37, 2482 (1915).

² Z. physik. Chem., 14, 192 (1923).

Initial readings had to be taken in each case with the desired concentration of sugar and salt present, because it was found that the salts decreased the rotation of the sugar. The algebraic sum of the initial and final readings gave the total change. The percent sugar present at the time t was found as follows:

$$\% \text{ Sugar} = \frac{\text{reading at time } t - \text{final reading}}{\text{total change in readings}} \times 100$$

The reaction velocity constant was calculated by the following equation, using percent to express concentrations,

$$.4343 k = 1/t \log_{10} \frac{100}{\% \text{ Sugar}}$$

The results which are given in Table III are the means of a series of values of k of which the data in Table II are typical.

4	.3700 (approx.)	620	733

In the cases of 3 N NaCl and 4 N NaBr the constant obtained was not satisfactory so these values are only approximate. The iodide solutions could not be followed on a saccharimeter because the solution became so colored that sufficient light did not come through the solution to obtain an accurate reading.

Upon comparison of the results obtained by the two methods it is seen, that the percentage increase, for the same normality of salt, in the reaction velocity agrees, within the limits of experimental error, with the percentage increase as given by the electrometric method. The percentage increase as given by the 4N bromides does not agree very well but the value of k for this concentration of salt in the sugar inversion is only approximate.

Hydrolysis of Ethyl Acetate

On examining the literature¹, it was found that the results obtained by the hydrolysis of ethyl acetate did not agree with those obtained by the inversion of sugar, in the case of sodium chloride. Åkerlöf's experiments were then repeated, using 0.1 N hydrochloric acid instead of 0.05 N. This concentration (0.1 N) was the concentration of HCl used in the former experiments. The reaction velocity of the hydrolysis of salt-free 0.05 molar ethyl acetate in the presence of 0.1 N HCl was determined. Then the reaction velocity of the same mixture with the addition of two and four normal sodium chloride was measured.

The ethyl acetate used was Kahlbaum's C.P. It was purified by washing three times with a 5% solution of sodium carbonate and then dried for two days over calcium chloride. It was then redistilled, a constant-boiling product being obtained. Only the middle fraction of the distillate was collected. The ethyl acetate was placed in a tightly-stoppered bottle which was then kept in the thermostat. The stock bottle of the acid and the measuring flask containing the salt in solution were kept in the thermostat so that all the solutions were at the same temperature when mixed. In all the experiments, with the exception of the last one, one cc. of pure ethyl acetate was added to the salt and acid solution and the whole diluted to 200 cc. giving 0.05 molar ethyl acetate and 0.1 N HCl. 10 cc. samples were withdrawn at intervals and run into 10 cc. of sodium acetate solution (0.5 N) to stop the reaction. The excess acetic acid formed and the HCl present were titrated with CO₂-free sodium hydroxide, using phenolphthalein as an indicator. The samples were withdrawn by means of a special pipette arrangement consisting of a 10 cc. pipette sealed on to a capillary stop-cock (two-way). This was sealed on the single-arm side of the stopcock. One of the other arms dipped into the solution in the reaction mixture through a tightly-fitting rubber stopper. The third arm was drawn out into a tip close to the stop-cock and was used as the delivery tube. The beginning titre was taken in each case with the desired amount of salt present in the acid. These samples were also titrated in the presence of the 10 cc. of 0.5 N sodium acetate. The end-point of the reaction was found by sealing some of the solution in a tube and heating in a

¹ Åkerlöf: *Z. physik. Chem.*, **98**, 260 (1921).

water bath at about 75°C. for 12 hours. The tube was then placed in the thermostat and allowed to cool for the same length of time. The velocity constant, k , was found by the following equation:

$$.4343 k = 1/t \log_{10} \frac{A - x_0}{A - x_t}$$

where A = end titer in cc. of NaOH, x_0 = titer when the time $t = 0$, x_t = titer at time t , and t = time in hours. The data are given in Table IV.

TABLE IV
Effect of NaCl on the Rate of Hydrolysis of 0.05 M Ethyl Acetate
in the Presence of 0.1 N HCl.

These results are approximately the same as Åkerlöf's so it is to be concluded that this reaction is affected differently by the change in solvent, the

reaction velocity of this hydrolysis not being increased as much as in the case of sugar inversion. This is to be expected because we are dealing with different chemical substances and it is not likely that these would be affected the same by a change in the solvent.

On conducting some experiments on the effect of bromides on this reaction, Table V, it was found that they did not give as much increase in the reaction velocity as the chlorides. This should not be the case. If the bromides gave more of an increase in the one reaction, they ought to in all reaction, unless some other complicating factor enters into the reaction¹.

The experiments on the two normal sodium chloride and sodium bromide solutions were then repeated. Checks were obtained in the case of the chloride. The bromide gave a still lower value of k than the first trial. An average of these two was taken as the correct value.

TABLE V

Effect of NaBr on the Rate of Hydrolysis of 0.05 M Ethyl Acetate in the Presence of 0.1 N HCl.

Poma² agrees with these results in his study of the hydrolysis of ethyl acetate. He finds that the accelerating influence decreases in the order Cl, Br, NO₃, I.

It is evident that in the case of the bromides some substance in the reaction mixture was affecting the acid or the salt so that their accelerating influence was decreased. To find the disturbing factor the reaction was run with 1st 0.1 molar ethyl alcohol, 2nd 0.1 acetic acid present in the reaction mixture from the start. Both of these are products of the reaction. The data are given in Table VI.

¹ Iodides increase the solubility of ethyl acetate in water, according to Glasstone and Pound: J. Chem. Soc., 127, 2660 (1925).

² Gazz., 41 I, 353 (1911).

TABLE VI

Effect of Ethyl Alcohol and Acetic Acid on the Rate of Hydrolysis of 0.05 M Ethyl Acetate in the Presence of 2 N NaBr and 0.1 N HCl.

7	.0566		
7.5	.0597		

It can be seen that the addition of alcohol or acetic acid had little or no effect on the reaction velocity. However, it was noticed that the value of k obtained in all the reactions with bromides was not constant, but rose steadily, with a few exceptions, as the reaction proceeded. From this it is apparent that it must be the ethyl acetate which is affecting the reaction. For, as it decreases, due to reacting with the water, its inhibiting effect decreases, and the reaction velocity increases. An experiment was then made with 0.1 molar ethyl acetate instead of 0.05 molar. The mean value of k , for the length of time the other experiments were run, was 0.0511 or only a 22% increase. If it was the ethyl acetate that was slowing up the reaction, as this last experiment seems to indicate, the value of k ought to increase until, as the time approaches infinity, it reaches at least the value of k obtained with the chlorides. The reaction was then continued, taking readings up to 32 hours, Table VII.

As seen by Table VII, the value of k did increase, by that time, to the value obtained with the chloride, i.e. .0590. This value of k would probably continue to rise, for 32 hours does not represent infinity. The titre in cc. of NaOH had increased in 11 hours after the reading at 32 hours only from 19.6 to 20.48. The final end-point titre was 21.2 cc. and this was not reached until several hours later.

TABLE VII

Hydrolysis of 0.1 Molar Ethyl Acetate in the Presence of
2 N NaBr and 0.1 N HCl.

Time in Hours	k	Time in Hours	k
1.5	.0482	13	.0547
2	.0499	14	.0549

11	.0537	32	.0590
12	.0558		

Mean of first 8 = .0511 = 22% increase

The work of Glasstone and Pound¹ on the effect of salts on the solubility of ethyl acetate in water indicates that bromides do not decrease the solubility of ethyl acetate in water as much as chlorides, and iodides less than bromides. In fact, lithium bromide and iodide *increase* the solubility of ethyl acetate in water till, with the 60% lithium iodide, ethyl acetate and water are miscible in all proportions! In general, bromides and iodides are more soluble in ethyl acetate than are chlorides. These two effects would tend to prevent bromides from having as much effect on the reaction velocity as chlorides.

This work was undertaken at the suggestion of Professor W. D. Bancroft, and carried out under his direction. To him the writer wishes to express his sincere appreciation.

The writer also wishes to thank Dr. G. H. Brandes for his aid in the electrometric measurements.

NEW BOOKS

Science Religion and Reality. Edited by Joseph Needham. 22 × 15 cm; pp. 396. New York: The Macmillan Company, 1925. Price: \$2.50. The book opens with an introduction by Lord Balfour and closes with a conclusion by Dean Inge. In between are articles entitled: Magic Science and Religion, by Bronislaw Malinowski; Historical Relations of Religion and Science, by Charles Singer; Science and Religion in the Nineteenth Century, by Antonio Aliotta; The Domain of Physical Science, by Arthur Eddington; Mechanistic Biology and the Religious Consciousness, by Joseph Needham. The Sphere of Religion, by John W. Oman; Religion and Psychology, by William Brown; Science Christianity and Modern Civilisation, by Clement C. J. Webb. Some of us would like more commas; but the omissions seem intentional.

"The conception of a material universe, overwhelming in its complexity and its splendour, yet potentially susceptible of complete explanation by the actions and reactions of two very minute and simple kinds of electrical sub-atom, is, without doubt, extraordinarily fascinating. From the early days of scientific philosophy or (if you prefer it) of philosophical science, thinkers have been hungering after some form of all-embracing atomism. They have now apparently reached it (so far as matter is concerned) by the way of observation and experiment—truly a marvellous performance. Yet the very lucidity of the new conceptions helps to bring home to us their essential insufficiency as a theory of the universe. They may be capable of explaining the constitution and behaviour of inanimate objects. They may go some (as yet unmeasured) distance towards explaining organic life. But they certainly cannot explain mind. No man really supposes that he personally is nothing more than a changing group of electrical charges, so distributed that their relative motions enable or compel them in their collective capacity to will, to hope, to love, to think, perhaps to discuss themselves as a physical multiplicity, certainly to treat themselves as a mental unity. No creed of this kind can ever be extracted by valid reasoning from the sort of data which the physics either of the present or the future can possibly supply," p. 14 (Balfour).

"When we examine the literary monuments of the classical culture—of which we are the heirs and the Greeks the earlier and main intellectual representatives—we cannot fail to be impressed by the vastness of its interests, the enormous mental energy that it displays and the bulk and completeness of its remains. Considering these things the comparative backwardness of the religious development of that culture is a very striking feature. Greek religion—using that word in the restricted sense—never reached the rational standard of the Hebrew religion. Thus no complete and worked-out Greek cosmology, incorporated in a religious atmosphere, has come down to us. The popular Greek religion, in fact, never reached the coherent level of the Hebrew, or reached it only in later times and then in competition with philosophical or other systems which themselves made religious claims, and notably in contact with Christianity. . . .

"The absence of a sacred Canon and the relatively low grade of their religion is in contrast to their scientific and philosophical development for which, as some think, way was thus made. At a remarkably early stage in their development the Greeks observed not only that their world was subject to laws, but that by investigation these laws are ever further and further discoverable. A belief in such natural laws plays no part in the more ancient Hebrew scriptures, which, moreover, contain very little of that curiosity which is the parent of science. It was with the Ionian Greeks that the scientific idea was born, and it can be traced back among them with some clearness to the sixth century B. C.," p. 91 (Singer).

"It was thus not the *practice* of science which the Greeks invented, but the *scientific idea*, the conception that the world was knowable inasmuch and in so far as it could be investigated. In ancient times this idea led to a special point of view and to some amelioration of man's lot. In modern times it has led to a complete transformation of our mode of life, to a profound modification of the interrelations of peoples, and to an alteration in our

attitude to each other and to the world around us. It would be idle to pretend that these changes have been entirely to the good. We believe, however, that an impartial survey of the general effects of the scientific idea upon men's minds and hearts throughout the ages will result in an overwhelming verdict in its favour as a very beneficent and humanising instrument. In helping man to gain a clear idea of the knowable world, science has also helped him to understand his fellow-man," p. 92 (Singer).

"The physical philosophers of the fourth century, of whom Aristotle is the greatest and most permanent type, were more successful than Plato in their efforts at constructing a coherent and lasting cosmic theory. We may glance at the picture of the material universe presented by Aristotle. That great thinker was himself an absolutely first-class naturalist. Thus the cosmic scheme that he produced, unlike that of Plato, absorbed a vast mass of observational material, notably in the department of biology. Yet the bases of the scheme were certain preconceived notions which did not and could not depend upon observation. Into this scheme observations had to be fitted. The difficulty of fitting them represents a struggle between the observational and theoretical interests which is a prototype of that so often encountered in later centuries," p. 101 (Singer).

"Despite the spread of philosophy based on science, the observational activity of antiquity was slowly dying from about 100 B. C. In A. D. 200 it expired with Galen. The decay of observation, as we have seen, was the result of internally acting causes. In origin it had nothing to do with Christianity, which was not yet in a position to have its full effect on pagan thought.

"But Christianity did come as a protest and a revulsion against the prevailing and extremely pessimistic outlook. Men had lost interest in the world and Christianity brought them something to live for, it brought a *cause*. It was natural under these circumstances that Christian thought should oppose the philosophical basis of pagan thought. In this sense early Christian thought was certainly anti-scientific and exhibits an aversion to the view which places the whole of man's fate under the dominion, the inescapable tyranny, of natural law. It is, however, essential to remember that the Early Church in developing this opposition was not dealing with living observational science. The conflict was simply with a philosophical tradition which contained dead, non-progressive, and misunderstood scientific elements. The conflict in the Early Church, therefore, though exceedingly interesting in itself, is of little importance for our subject and we can afford to pass it by.

"As the centuries wear on and as Christianity becomes more firmly established as the state religion, the need for a coherent philosophical system becomes more pressing. During the earlier Middle Ages this need is met on the scientific side largely by that bizarre work of Plato, the *"Timaeus."* As time goes on Aristotelian elements become more and more prominent, and by the thirteenth century these Aristotelian elements occupy the main field. The great system of Catholic philosophy, of which St. Thomas Aquinas was the leading architect, was built upon the recovered writings of Aristotle. The work of Aquinas is merely the greatest and most lucid effort of a process that had been going on for centuries. His *"Summa Theologica,"* regarded as a sustained intellectual effort, must be considered one of the most remarkable and fatiguing performances that the human race has yet achieved. As an investigation of evidence for the views that it sets forth, the modern working scientist will pass it by," p. 114 (Singer).

"But it may be asked, was there then no science in the Middle Ages? Were none of the heresies, for instance, with which the Church had to deal of the nature of scientific hypotheses? To answer this question is difficult, and yet we must attempt it. To answer it with completeness we should have to define what we mean by science and this would lead us far afield. We may note, however, that science in its most developed form exhibits certain characteristic features.

"(a) It deals with judgments to which universal assent is obtainable.

"(b) It is a consciously progressively increasing body of knowledge and doctrine.

"(c) The only tests of validity that it can accept are the tests of experience, and these tests it must always demand.

"(d) An essential process of science is the drawing up of general laws from the results of observation.

"(e) It is necessary for the growth of science and is perhaps a corollary of the other features that the conclusions, being based on the evidence, should not be prejudged.

"Now a fixed and definite scheme of the Universe was accepted as a postulate by all thinkers of the Middle Ages. That scheme was derived from Aristotle but modified to fit the specific Christian doctrine of creation. With these things always before the mind, scientific investigation in our sense of the word was almost impossible to the medieval man. He could never embark on that great voyage of exploration with the sense of infinite possibilities which is the birthright of every young researcher nowadays," p. 117 (Singer).

"During the thirteenth century there was much interest in optics; the attention devoted to the subject led in about the year 1300 to the application of lenses—which had been known to the Arabian writers—as spectacles. A similar process had led at an even earlier date to the adaptation of the magnet to the mariner's compass. These are discoveries of first-rate importance and we cannot pass them by in silence. But—and this is where we sense the characteristic medieval atmosphere—*these discoveries led to the production of no general laws*. The lens led to no advance in the doctrine of refraction or in the theory of light. The compass revealed nothing of the nature of terrestrial magnetism to the medieval thinker. They were on the level of *inventions* rather than definite steps in scientific progress. The actual application of these discoveries was far more important to the men of the time than were the principles involved. If we seek for interest in the eliciting of new general laws of nature we shall have a long and fruitless hunt in the vast wilderness of time that we call the Middle Ages," p. 119 (Singer).

"The Inquisition as a separate, regular, and legally established method of establishing faith and uprooting error makes its appearance in the thirteenth century. Our horror at its methods, our indignation at its injustice, our detestation of its blood-stained and infamous history, must not mislead us into regarding it as an attack on the experimental method, or as a means of suppressing at its birth a monster which if allowed to live and grow would one day strangle religion. There can be no reasonable doubt that in the sixteenth, seventeenth, and eighteenth centuries the activities of the officers of the Inquisition were directed to the suppression of scientific views that were held to be dangerous to the faith. In the centuries that preceded, however, no such tendency can be distinguished. The reasons for this are simple. During those earlier centuries, on the one hand experimental methods produced no conclusions that were dangerous to current theology, and on the other it is extremely unlikely that any officer of the Inquisition ever grasped the nature of the scientific method. So far as the Middle Ages are concerned we can therefore put aside the Inquisition as irrelevant to our discussion," p. 121 (Singer).

"To us who live only a generation or two after the disturbances of the spirit caused by the Evolution controversy, it may seem that biological rather than physical science is the department likely to clash with the claims of traditional religion. Yet historically this is not the case. The successors of Vesalius continued to prosecute their studies until the nineteenth century unnoticed or even directly aided by the Churches. It was the cosmical speculations of the astronomers and physicists, not the investigations of the biologists, that attracted unwelcome ecclesiastical attention," p. 129 (Singer).

"Historically men of science have found various modes of escape from the tyranny of determination. The majority of men of science, like the majority of other men, have small philosophical powers. They, like most other men, have accepted their religion as they have found it. They have made their science their daily occupation without clear relation to their religious convictions. A proportion of scientific men, incensed by the mere discrepancy between the biblical and the scientific record, have abandoned more or less completely their relation to religion. A considerable section of these have ranged themselves as 'agnostic.' Yet there remain two religious points of view that can never be affected by any extension of the scientific realm. The one would completely separate internal experience from external experience. The man who does that is safe; he has fled, as have many before him, to a haven of peace down the mystic way. The second would regard man's soul not alto-

gether as his own possession, but as part of a great world-soul. This combination of de termination and pantheism is a refuge, not infrequently sought in antiquity, to which many a student of science has turned in modern times, from the days of Spinoza onward," p. 148 (Singer).

"The confession of impotence by agnostic naturalism led, towards the end of the century, to a return to the romantic spirit of the beginning of the century. Science, of which Positivism had been the first to proclaim the apotheosis, was submitted to criticism, and revealed the abstraction of its concepts and of its theories, which do not make us gather the reality of its living richness, but only the skeleton of it. It was found that those theories are also at bottom a human construction, variable and relative, and that they suppose an act of faith at their roots. In this way the distinction between pure reason and practical reason which Kant had made was shown to be artificial, because the activity of the scientists is itself directed to a practical end; that is, to that of dominating nature, of finding suitable schemes which may serve to guide us through the complexity of the phenomena of experience. Thus religion and science were reconciled in their common origin, which is always an act of free will, a free adhesion of the spirit; and dualism was superseded.

"According to Pragmatism, of which William James and F. C. S. Schiller are the most illustrious representatives, the sole function of science is to serve for action, to provide us with methods to follow in order that we may see this or that phenomenon appear, or in order that we may obtain this or that result. A proposition which does not generate practical results has no meaning. Two propositions which bring no result in their manner of acting differ only verbally. According to the Pragmatist, there is no truth which must be reflected from without, or to which the thought must correspond to be called true. Truth and reality are constructed actively by ourselves. There exists no perfect system laid down *ab aeterno*, with immutable laws; but reality is always on the road towards being made, a ceaseless creation, in which we collaborate with our energetic forces," p. 166 (Aliotta).

"The learned physicist and the man in the street were standing together on the threshold about to enter a room.

"The man in the street moved forward without trouble, planted his foot on a solid unyielding plank at rest before him, and entered.

"The physicist was faced with an intricate problem. To make any movement he must shove against the atmosphere, which presses with a force of fourteen pounds on every square inch of his body. He must land on a plank travelling at twenty miles a second round the sun—a fraction of a second earlier or later the plank would be miles away from the chosen spot. He must do this whilst hanging from a round planet head outward into space, and with a wind of ether blowing at no one knows how many miles a second through every interstice of his body. He reflects too that the plank is not what it appears to be—a continuous support for his weight. The plank is mostly emptiness; very sparsely scattered in that emptiness are myriads of electric charges dashing about at great speeds but occupying at any moment less than a billionth part of the volume which the plank seems to fill continuously. It is like stepping on a swarm of flies. Will he not slip through? No, if he makes the venture, he falls for an instant till an electron hits him and gives a boost up again; he falls again, and is knocked upwards by another electron; and so on. The net result is that he neither slips through the swarm nor is bombarded up to the ceiling, but is kept about steady in this shuttlecock fashion. Or rather, it is not certain but highly probable that he remains steady; and if, unfortunately, he should sink through the floor or hit the ceiling, the occurrence would not be a violation of the laws of nature but a rare coincidence.

"By careful calculation of these and other conditions the physicist may reach a solution of the problem of entering a room; and, if he is fortunate enough to avoid mathematical blunders, he will prove satisfactorily that the feat can be accomplished in the manner already adopted by his ignorant companion. Happily even a learned physicist has usually some sense of proportion; and it is probable that for this occasion he put out of mind scientific truths about astronomical motions, the constitution of planks, and the laws of probability, and was content to follow the same crude conception of his task that presented itself to the mind of his unscientific colleague," p. 189 (Eddington).

"The central point of Einstein's great theory is a new law of gravitation approximating to but more accurate than Newton's law, and we shall start by explaining exactly the formulation of this law. Our explanation will be more thorough than usual, for we shall make a point of defining each new term that it is necessary to introduce. Probably the effect of giving so full an explanation will be that the reader will not understand the new law any better at the end than he did at the beginning. That does not matter. He is asked to keep his attention fixed on the form of the explanation rather than on the substance of the explanation; we want to indicate to him the train of ideas that he would have to exhaust if he wished to get to the bottom of the significance of the new law.

"Einstein's law of gravitation is a statement that in empty space ten quantities called *potentials* satisfy certain rather lengthy mathematical equations which can be exactly specified. (The term "potential" will be explained presently.) In other words, whereas we might conceive a world in which the potentials at every moment and at every place had entirely arbitrary values, the actual world around us is not so unlimited. The statement that actual phenomena are more limited in variety than imaginable phenomena is evidently equivalent to the statement that the actual world is governed by a law. The next question is, What are the "potentials" which are governed by the law that has been specified? They are derived by simple mathematical calculations from certain other quantities called *intervals*. If we know the values of the various intervals through the world we can at once find the potentials. What are these "intervals"? They are relations between pairs of events which are measured by the *scale* or *clock*. Instructions can be given describing exactly how the scale and clock are to be employed, and the interval is merely the scale-reading or clock-reading or a particular combination of the two readings. Next question, What are "scales" and "clocks"? It would take a somewhat long description to prescribe exactly what constitutes a perfect scale or clock referred to here, but with patience all the requirements can be stated; we should, however, find it necessary to introduce a new word which ought to be carefully explained—the scales and clocks are made of *matter*. Next question, What is "matter"? That has often been asked, with many diverse answers; but here the answer is not so difficult. Metaphysical properties of substantiality have no bearing on the efficiency of a clock as an instrument of measurement, it is only the mechanical properties of matter which concern us here; and, so far as mechanics is concerned, matter is merely the embodiment of three measurable entities, *mass*, *momentum*, and *stress*. What are "mass," "momentum," and "stress"? It is one of the remarkable (though comparatively little known) achievements of Einstein's theory that it has succeeded in describing exactly what these are. They are certain analytical expressions containing various combinations of the *potentials*. What are the "potentials"? Why, that is just what I have been explaining to you!

"The definitions of physics proceed according to the method immortalised in "The House that Jack Built": *This is the potential, that was derived from the interval, that was measured by the scale, that was made from the matter, that embodied the mass.* . . . But instead of arriving ultimately at "Jack," whom, of course, everybody knows without need of introduction, we make a circuit back to the beginning of the rhyme . . . "that killed the rat, that ate the malt, that lay in the house—that was built by the priest all shaven and shorn, that married. . . ." So now we can go around and round for ever," p. 203 (Eddington).

"Actuality is recognised as tremendously important by the experimental physicist. But it does not appear in the scheme of the theoretical physicist. And it is quite natural that it should not appear. The experimental physicist deals with the particular cases; the theoretical physicist generalises; he refines away that which is special and particular and seeks to obtain the general laws of nature. So that he eliminates the reference to one particular and actual world and arrives at a theory which applies to all possible conditions that might occur—this, of course, includes the actual world as a special case. The theoretical physicist thus necessarily excludes actuality from his purview, though he arranges that it can be added as an afterthought; and we can see how admirably the device of the

vicious circle of definition is adapted to this purpose, because if actuality is added at any point it runs throughout the whole cycle. If our potentials are actual, then our matter, clocks, scales, intervals, etc., will all become actual.

"Theoretical physics leaves room for actuality to be added, but it cannot itself tackle the question. It makes no attempt to define actuality. The experimental physicist, for whom actuality is vitally important, has to turn elsewhere, and he turns to consciousness. He simply accepts as actual that which the mind recognises as actual. He is alert for criticism of the reliability of his scales and clocks, but he has no misgivings as to their actuality. It is, of course, not necessary to appeal to the mind in each particular instance; when once actuality has been introduced at any point of the cycle it runs through the whole cycle. But to obtain a start we must be given something certified as actual by the mind," p. 210 (Eddington).

"Some reference must be made to the time-long difficulty of understanding how a man can voluntarily produce or refrain from producing effects in the physical world without (so experiment teaches) setting aside any of the laws known to govern inorganic nature. The difficulty is undoubtedly a grave one, and we cannot offer a solution of it; but it is somewhat modified by the newer conception of the nature of the laws governing the physical world. In the present stage of science the laws of physics appear to be divisible into three classes—the identical, the statistical, and the transcendental. The 'identical laws' include the great field-laws which are commonly quoted as typical instances of natural law—the law of gravitation, the law of conservation of mass and energy, the laws of electric and magnetic force, and the conservation of electric charge. These are seen to be identities, when we refer to the cycle so as to understand the constitution of the entities obeying them; and unless we have misunderstood this constitution, violation of these laws is inconceivable. They do not in any way limit the actual basal structure of the world, and are not laws of governance. To quote again from Professor Weyl, "The freedom of action in the world is no more restricted by the rigorous laws of field physics than it is by the laws of Euclidean geometry according to the usual view." You have unfettered freedom to draw anything you like on a flat sheet of paper; all the same, you cannot draw a circle whose circumference is six times its diameter. But you would not complain that because of this inability to do impossible things your freedom is imperfect. The law of Euclidean geometry is not felt to be a restriction on the freedom of the artist; similarly the law of gravitation, when the nature of that which obeys it is understood, cannot be regarded as a limitation of freedom. The 'statistical law,' including the laws of gases and thermodynamics, are the laws obeyed by crowds independently of the characteristics of the individuals composing the crowds. There remain the 'transcendental laws,' namely, the laws of atomic structure and of the quantum theory, which so far as we know may be true laws of governance. The quantum theory, perhaps even more than the relativity theory, is a remarkable development of the last twenty years, constituting an amazing breach with the traditional type of physical theory. It includes certain precise laws confirmed by innumerable experiments in all branches of physics, but no one has succeeded in forming an intelligible conception of the quantum processes. One thing is generally accepted, that we have here entered a domain of law of a type to which our experience of the great laws belonging to the first class gives no clue.

"Interference of human free will with the identical laws cannot be admitted; even omnipotence could scarcely set these aside, and free will does not mean omnipotence. It must be statistical or transcendental laws that are modified when we "make up our minds" to do something. It would be a comfortable theory if we could lay the whole blame of free will on the transcendental laws—particularly on those which have not yet been discovered! But I fear that there can be no satisfactory theory of free will without admitting an interference with statistical laws. If a human being can produce motion of material objects as the result of a mental resolution—motion which would not have resulted from the automatic interplay of electrons and atoms in his brain and body—it seems clear that those electrons and atoms are for the time not behaving as an ungoverned swarm would do, and some at least of the statistical laws governing random crowds will fail to hold. Indeed, the mind

must necessarily have its grip on the crowd rather than on the individual atom or quantum-process, for the contact of matter and spirit is between brain and mind and not between an atom of brain and a (conjectural) atom of mind. If the physical aspects of what is occurring conform to statistical laws, the mental resolution itself must be governed by statistical laws, and is therefore not what it appears to be—a simple decision of will—but a conflict of billions of unrecognised mental elements.

"The serious difficulty arises that at present no failure of the statistical laws has been detected in experiments made on living organisms, and that the chief of these laws—the second law of thermodynamics—has been verified with some accuracy. Whilst this difficulty is perhaps not insuperable, it must not be minimised," p. 214 (Eddington).

"It is usually considered in this present age of universal specialisation that the business of men is to speak only about their own affairs, and, if they have any world-outlook, to keep it to themselves. Particularly is this the case with the scientific worker; but he is not alone in his mental prison. There adjoins it another, equally commodious but equally well bolted from outside, which is inhabited by the theologian and the mystic. In fact, there is a whole honeycomb of cells, each containing a section or two of human thought and experience, and the prison is so constructed that whatever opinions the inmates may have about each other, whenever they happen to open their mouths thereon they are miraculously struck dumb," p. 221 (Needham).

"The ever-rising tide of specialisation has obscured the fact that there are not a few problems, especially in the fields of pure knowledge, which cannot be understood in the terms of one subject. The spectrum of knowledge has been arbitrarily divided up into compartments, whereas the colours really shade into each other quite imperceptibly. Such arbitrary cuttings and slicings have often mutilated the delicate fabric of reality, with the result that there are many questions at the present time most urgently needing the synthesis of two or more illuminations. As an example we might adduce our knowledge of the nervous system of man. It has been studied from three main directions: experimental psychology has examined it, biochemistry has studied its metabolism and its chemical composition, and biophysics has collected data about its electrical phenomena. But no one has yet synthesised these items of knowledge into one unitary whole," p. 222 (Needham).

"Physiology, which had had little to say to the evolution theory, since taxonomic classification had been founded on differences of form rather than of function, now began to occupy more and more the centre of the field, and as this process went on it was seen that physiology wore no longer the garments in which traditional teaching had pictured her, but appeared in the breast-plate of chemistry, the helmet of physics, and armed with the spear of mathematics. As time went on the hitherto neglected subject of biochemistry became more and more important, so that at the present day zoology has become comparative biochemistry and physiology biophysics. The causes for the change lie deep, but the effect has been profound infiltration of physico-chemical ideas and terminology into the whole biological field, and this implies a corresponding peaceful penetration of the mechanistic theory of life. This change from comparative morphology to comparative biochemistry is indeed one of the most important factors in the scientific history of the last few decades. It will never again be equalled in importance until comparative biochemistry passes over into electronic biophysics. For it means that we have passed one step deeper into the problem of life—important as the distribution and form of organisms may be, it cannot be so much so as the actual examination of the physico-chemical attributes of living matter itself, of the universal substrate of the innumerable manifestations of living beings. The forms of the different types of sea-urchins are truly most interesting, but they are only the form taken by the same chemical elements, and in this case as in others the body is more than the raiment," p. 224 (Needham).

"At the present day then the situation is in effect the complete triumph of mechanistic biology. It is not alone in the field, because the neo-vitalists do exist as a small minority, but the vast preponderance of active biological workers are mechanists. We have already given four instances of the antagonism between theology and mechanistic biology, and we can now add a fifth. At the Modernist Conference held at Oxford in the summer of 1924

all the speakers on biological subjects were professed and eminent vitalists. Nothing could be more beautifully in line with the traditional manner. But although it is possible to understand the alacrity with which the theological mind greets vitalistic and spiritualistic ideas in biology, yet it may be doubted whether, even from a narrowly apologetic point of view, it was wise to nail the colours of religion to the precarious mast of neo-vitalism," p. 235 (Needham).

Wilder D. Bancroft

The Hydrous Oxides. By Harry B. Weiser. 21 X 14 cm; pp. x + 452 New York and London: McGraw-Hill Book Company, 1926. Price: \$5.00. In the preface the author says: "No group of substances presents a greater variety of colloidal properties than the hydrous oxides. For this reason they have been employed frequently in the investigation of colloid chemical phenomena and applied in widely diversified ways to the industrial arts. There is little doubt that a more intimate acquaintanceship with this group of substances will serve to extend their field of usefulness rapidly. It is hoped, therefore, that the book may prove of value alike to scientist and industrialist." The subject is treated under the general heads: jellies and gelatinous precipitates; the hydrous oxides of iron; hydrous chromic oxide; the hydrous oxides of aluminum, gallium, indium, and thallium; the hydrous oxides of copper, cobalt, nickel, silver, and gold; the hydrous oxides of beryllium, magnesium, zinc, cadmium, and mercury; the hydrous oxides of silicon and germanium; the hydrous oxides of tin and lead; the hydrous oxides of titanium, zirconium, and thorium; the hydrous oxides of the rare earths; the hydrous oxides of the fifth group; the hydrous oxides of molybdenum, tungsten, and uranium; the hydrous oxides of manganese; the hydrous oxides of the platinum family; tanning; mordants; water purification; cement; the soil.

It is interesting to note that a century ago Rose observed that glycerol, mannite, sucrose, and glucose will prevent the precipitation of hydrous ferric oxide on adding of alkali or ammonia to a solution of a ferric salt. A small amount of hydrous ferric oxide inhibits the crystallization of cane sugar to such an extent that a high percentage of molasses is obtained in plant work if the raw sugar is kept in iron vessels or if the clearing 'char' contains iron, p. 44. Wintgen calculates that one micelle of aged iron oxide sol is balanced electrically by over ten thousand chlorine ions, p. 51.

"The adsorbability of the alkalis deduced from their power to cut down the adsorption of barium ion is in the order : $K > Na > Li$. From the curves in Fig. 7 it will be seen that the precipitation value of barium chloride is increased by like amounts of alkali chlorides in the order $LiCl > NaCl > KCl$; while in the presence of HCl , the precipitation value of barium salt first rises to a point just below that in the presence of a like amount of lithium chloride and then drops off rather sharply. The following explanation of these phenomena is suggested: For a given alkali chloride concentration, precipitation will take place when the combined adsorption of the two cations neutralizes the combined adsorption of chloride and hydrosulfide ions. The combined adsorption will be equivalent for different pairs of cations; but the relative amounts of each that make up this equivalent adsorption will vary, depending as it does on the relative adsorbability of the two cations. If one may disregard for the moment the slight variation in the amounts of chloride added with barium chloride as compared with the relatively large amount of this ion added with the alkali chloride, it follows that, for a given concentration of different alkali chlorides, the varying amounts to barium that must be added will depend on the effect of each cation on the adsorption of the other. Thus, the adsorption of barium is cut down by lithium ion less than by potassium ion, tending to make the precipitation concentration of barium chloride less in the presence of lithium chloride than of potassium chloride. Hand in hand with this is the decrease in the adsorption of alkali by barium, which will tend to make the precipitation concentration of barium chloride higher in the presence of lithium. From this point of view, the latter factor appears to predominate with the alkali chlorides. With hydrochloric acid, however, the cutting down of the adsorption of barium by hydrogen ion is the determining factor with lower concentrations of hydrochloric acid; while with higher concentrations of acid the second factor appears to predominate," p. 99.

"Knowing the conditions favorable to jelly formation by precipitation of a negative colloidal hydrous chromic oxide, it is a simple matter to precipitate the positive sol as a jelly. All that is necessary is to add just enough electrolyte to cause complete coagulation in an hour or two. If too little electrolyte is used, precipitation is incomplete and the results are unsatisfactory; while if too great an excess is added, the precipitation is so rapid that a gelatinous precipitate is formed. From the results recorded in Table X, it is quite evident that jellies will form in the presence of any precipitating ion. Moreover, the hydrogen concentration within which jellies will form, can vary over a wide range; thus, they are obtained from strongly alkaline solution and from a colloid stabilized by hydrogen ion," p. 102.

"Recently Willstätter and Kraut described a number of hydrous oxides differing in reactivity and adsorptive power, by precipitating aluminum sulfate with ammonia: With concentrated ammonia, and boiling for a long time, the precipitate was a pale yellow plastic mass *A*; without prolonged boiling, it was a very pale yellow plastic mass *B*; with dilute ammonia it was a pure white, very voluminous, and very finely divided substance *C*. An intermediate variety *b* prepared by the dialysis of aluminum chloride with frequent additions of small quantities of ammonia, was claimed to be related chemically to *B* but resembled *A* in adsorptive capacity; and a modified form of *C* precipitated at 60° had an adsorptive capacity similar to *B*. Specimens of *A* were entirely different in properties, depending on whether they were still moist or subjected to a rapid preliminary drying in a high vacuum over P_2O_5 ," p. 103.

"The adsorption of chromate by hydrous alumina is sufficiently strong to impart a yellow color to the precipitate formed in the presence of alkali chromate or precipitated and subsequently shaken with alkali chromate solutions. Charriou found little alkali metal in the precipitate and so attributed the color to the formation of aluminum chromate on the surface of the alumina. There is no justification for this conclusion and it is probably erroneous. If well-washed alumina is shaken with alkali chromate, the solution becomes alkaline owing to stronger adsorption of acid than of base. The yellow color is due to chromic acid rather than aluminum chromate. Ishazaka found that potassium dichromate was converted to chromate in the presence of powdered alumina," p. 126.

"It cannot be emphasized too strongly that comparative data on adsorption by hydrous alumina or any other substance cannot be obtained unless particular attention is paid to the physical character of the adsorbent. To make the most rapid progress it would seem to be essential for biochemists to get together on some well-defined arbitrary methods of procedure for making a series of preparations that could serve as standards. The systems with which the biochemists deal are so complicated at best that there seems no justification for carrying out adsorption experiments with adsorbents that are not standardized in some way," p. 129.

"Since a crystalline rose-colored oxide [of cobalt] is known with certainty, and there is only an analysis of an apparently amorphous mass to indicate the nature of the blue preparation, it might be concluded that the blue compound is a hydrous oxide and the rose, a hydroxide. This hypothesis, like that of Hantzsch's, cannot be correct, since it is based on the manner in which water is held by the oxide, and apparently we may have either a blue or a rose oxide in the absence of water. Thus cobalt glass owes its color to the blue anhydrous oxide; and the brown anhydrous powder obtained by drying the precipitated hydrate melts without decomposition and gives rose-colored crystals on cooling. This suggests the possibility of the color of cobalt oxide and hydroxide being determined by the size of particles. In glass the particles are obviously highly dispersed and appear blue, while the oxide in mass is red. Similarly, the precipitated oxide is most finely divided when first formed and so is blue; but in the presence of a slight excess of alkali, the highly hydrous mass ages, losing water and becoming denser, the color at the same time changing from blue through lavender to rose. The rate of this transformation is, of course, hastened by raising the temperature, and is retarded or stopped by the presence of basic cobalt salts or hydrous nickel oxide.

"If one objects to attributing the difference in color to the size of particles, an alternative hypothesis is that there are two allotropic forms of cobalt oxide, an instable blue one and a stable rose. As a matter of fact, the transformation of the blue gelatinous oxide to rose in the presence of alkali has led people to regard the former as the alkali-instable modification and the latter as the alkali-stable modification. The existence or non-existence of allotropic forms could probably be settled by comparing x-radiograms of the blue and rose oxides or hydrates," p. 149.

"In general, Patrick finds the adsorption of a solute to increase as its solubility in the solvent decreases. For example, the adsorption of benzoic acid from the several solvents is in inverse order of its solubility in these solvents. Similarly, formic acid is much more strongly adsorbed from toluene than is the more soluble butyric acid; iodine is adsorbed to a small extent in accord with the same laws. Moreover, nitrobenzene is adsorbed to a very great extent from kerosene with which it is only partially miscible, while benzene, which is much closer to kerosene in the solubility series, is adsorbed to a considerably smaller extent," p. 185.

"It should be pointed out that the capillary theory of adsorption is strictly applicable only in case there is not a specific adsorption factor in addition to the purely capillary phenomenon. Thus in the case of activated carbon the chemical polarity of the adsorbent cannot be disregarded and the results cannot be interpreted solely in terms of the physical nature of the capillaries. Moreover, the adsorption of solids from solutions does not come within the scope of the capillary theory," p. 188.

"Kramer finds that the addition of animal or vegetable oils to a 0.2 percent solution of sodium silicate gives a fine stable emulsion in which many of the drops exhibit Brownian movement. The fatty acid of the oil combines with the alkali to form soap, liberating colloidal silica which acts as a protective colloid for the emulsion. The careful addition of dilute hydrochloric acid produces a silica gel emulsion, while the addition of lime water causes coagulation forming a cheese-like coagulum and a thin liquid. These experiments are said to reproduce synthetically the changes in the tissue which take place in tuberculosis. Alkali silicate forms a fat emulsion in the tissues. The hydrous silica in the emulsion has a strong affinity for lime which is withdrawn from the blood and causes the caseation of the emulsified fat as in the experiments referred to above. Carbonic acid then acts slowly on the 'silica cheese,' converting the lime into carbonate, a process designated by the pathologists as calcification. There remains in the tissues the small amount of hydrous silica which served originally as the protective colloid for the emulsion. In line with this, Neyland found in tubercular lymph glands of oxen, a silica content of 0.27 gram SiO_2 in 1 kilogram of dry tissue while a calcified lymph gland contained 1.54 gram SiO_2 per kilogram of tissue," p. 195.

"There seems to be no real justification for postulating the existence of a wide variety of condensed stannic acids and complex basic salts. It seems much more likely, particularly in the light of the recent observations of Pascal and Yamada, that the various products are simply hydrous stannic oxides that have adsorbed hydrogen and chloride ions, the positive charge on the colloidal particle arising from preferential adsorption of hydrogen ion," p. 208.

"Probably the most interesting property of vanadium pentoxide sol is its double refraction on stirring, a phenomenon first observed by Freundlich and his pupils. If stirred with a glass rod and viewed in reflected light, an aged sol appears to be filled with yellow glittering streaks as if there were fine crystals suspended in it. In transmitted light, the sol remains clear, but dark streaks can be observed. Viewed between crossed nicols, the field remains dark as long as the sol is not disturbed; but stirring causes the field to become bright at once. By allowing the sol to flow between crossed nicols in convergent light parallel to the line connecting the nicols, an image is obtained of a crossed axis with concentric rings. Observed with a quarter-wave mica plate, the flowing sol behaves like a positive uniaxial crystal. Freundlich pictures the sol at rest as made up of elongated particles possessing the usual unordered Brownian movement which can give no double refraction. The setting up of directed motion causes the sol to lose its isotropic nature and to become double refracting. A section cut from the sol may be looked upon as having a space lattice somewhat similar to

a plate from an optically monoaxial crystal, the long axis of the sol particles coinciding in direction with the optical axis," p. 266.

"The double refraction in an aged sol is so strong that it can be demonstrated by allowing the sol to flow through a prismatic trough with a triangular cross-section and using this as a prism to decompose spectrum lines. In this way, the red hydrogen line is resolved into two oppositely polarized lines. The more strongly refracted ray vibrates parallel to the direction of flow of the sol, and in accordance with Babinet's rule, this extraordinary ray is more strongly absorbed than the other," p. 267.

"A mixture of perborate and permanganate may be added to bath water to make what is known as an 'oxygen bath'. The reaction in solution gives hydrogen peroxide and colloidal manganese dioxide, and the latter catalyzes the decomposition of the former, setting free oxygen which forms a supersaturated solution in the water and is subsequently evolved in small bubbles on the skin of the bather. The presence of electrolytes in the bath water was found to have such a marked effect on the rate of evolution of oxygen that Lottermoser investigated quantitatively the influence of various alkalies and salts on the decomposition of hydrogen peroxide by manganese dioxide. The impurity was added to the peroxide solution, after which the catalyst was prepared directly in the solution by adding permanganate and base in the order named. With salts of a common anion, different cations influenced the decomposition in the order $Ba^{++} > Sr^{++} > Ca^{++} > Na^{+} > K^{+} > Li^{+}$, barium ion accelerating it the most and lithium ion retarding it the most. Unfortunately, Lottermoser did not inquire into the reason for the accelerating action of certain electrolytes and the inhibiting action of others; but it is probable that this is very closely related to the adsorbability of the cations and to the variation in physical character of the hydrous particles formed in the presence of different electrolytes. Mg^{+} and NH_4^{+} ions were found to have a marked retarding action by cutting down the concentration of hydroxyl ion. For preparing a satisfactory oxygen bath, it is obviously necessary to avoid waters containing magnesium salts," p. 296.

"After championing the use of thermodynamic formulas to interpret tanning by tannin, one wonders why no attention whatsoever seems to have been paid to the phase rule in interpreting the results with chrome tanning. In the light of this generalization, the curves obtained by Thomas and Kelly certainly do not offer convincing proof of the formation of chromium collagenates. On the contrary, they indicate that quite the opposite is true," p. 330.

"The purification of water on a large scale is carried out with one or more of the following objects in view: first, to render the supply safe and suitable for drinking; second, to reduce the amounts of mineral ingredients which are injurious to boilers; and third, to remove substances injurious to the machinery or the manufactured product in industrial processes. The colloidal matter in surface waters consists of finely divided particles of clay, sand, organic coloring matter, and bacteria. Such material can usually be removed by agglomeration and filtering under suitable conditions. Undesirable dissolved substances such as the bicarbonates and sulfates of calcium and magnesium can be eliminated only by resorting to chemical precipitation. Many of the largest artificial water purification plants are operated solely to provide potable water without special attention to its use for industrial purposes. In other instances, the water is not only rendered potable but is softened at the same time. A notable example of the latter is the purification plant at New Orleans where hard, colored, turbid, sewage-polluted water from the Mississippi River is rendered suitable for industrial as well as domestic consumption.

"The most important requirement in the purification of a municipal water supply is the elimination of bacteria, especially those causing disease, and the removal of turbidity; but a perfectly acceptable drinking water is free from objectionable odor, taste, and color. Small amounts of the mineral constituents commonly found in water are not objectionable, as a rule, but certain ones are highly undesirable. Thus, the presence of as little as 2 p.p.m. of iron renders the water unpalatable to some people and causes trouble by discoloring wash-bowls and tubs, and by producing rust stains on cloth. It is needless to say that drinking

water must contain no more than a trace of salts of barium, copper, zinc, and lead, because of their poisonous character. Fortunately, the occurrence of harmful amounts of the latter salts in the ordinary water supply is quite rare," p. 366.

"In view of the importance of aluminum ion in the coagulation and removal of coloring matter, it would appear advantageous to treat highly colored waters at a low pH value where aluminum ions exist in solution as such, followed by increasing the pH value in order to precipitate all the aluminum. This is exactly what Norcom does with Cape Fear River water at Wilmington, N. C. The desired result is accomplished by connecting two sedimentation basins in series, treating the water with alum at a low pH value in the first basin, and increasing the pH value in the second basin by the addition of alkali," p. 378.

"Nitrogen in the form of nitrate is preferred by most plants; but, as already noted, the element cannot be stored as nitrate since the latter is so weakly adsorbed by the soil colloids that it is readily leached out and lost. The original source of nitrogen for plants, other than the legumes, is organic matter which is changed by the action of bacteria into ammonia and subsequently into the relatively strongly adsorbed ammonium salts. The latter transformation is a result of the soil acidity which is derived in large measure from the hydrolysis of salts and the relatively stronger adsorption of base than of acid by the soil colloids. Under the influence of bacteria, the small equilibrium concentration of ammonium salt is oxidized slowly to nitrate and becomes available for plant food," p. 404.

This is an admirable book. This reviewer has already found help in it for his research work and he expects to profit much more from it as time goes on. It is to be hoped that the author will continue his good work and will write about other salts, the sulphides for instance.

Wilder D. Bancroft

Magnetism and Atomic Structure. By Edmund C. Stoner. 22 × 15 cm; pp. xiii + 371. New York: E. P. Dutton and Company, 1926. "In this book an account is given of magnetic phenomena, and of the attempts made to interpret them in terms of the quantum theory which has been so successfully applied to the general problem of atomic structure. The basis of the quantum theory is still obscure, and its formulation uncertain, and there are many gaps and difficulties in its development. Some of these become especially prominent in magnetism, which was for long regarded rather as a stumbling-block for the quantum dynamical atomic theory. Closer consideration, however, shows that it actually yields remarkably strong support for it. It seems certain that the further study of magnetic phenomena, instead of undermining the quantum theory, will greatly strengthen it as a coherent whole, and will possibly throw light on its essential significance. For this reason, magnetism has at present an immediate importance much wider than that arising from its own intrinsic interest," p. vii.

The chapters are entitled: historical introduction; classical electromagnetic theory; experimental methods and survey of earlier results; the interpretation of magnetism as an atomic phenomenon; the quantum theory; survey of later experimental results—para- and ferro-magnetics; discussion of results—elementary moments and intrinsic fields; the gyro-magnetic effect; the magnetic deviation of atomic rays; the Zeeman effect; other magneto-optical effects; diamagnetism; miscellaneous magnetic effects; magnetism and the structure of the atom; magnetism and chemistry; problems—summary and conclusion.

"There was of course a difficulty in the simple electron theory of magnetism in that electrons rotating in orbits should radiate, according to classical theory. For this and other reasons there have been many abortive speculations centering round the view that the electron, even when not rotating in an orbit, is also a magneton—consisting, that is, of a swirl of electricity with the properties of a magnet. These views, frequently ingenious, and of mathematical interest, will not be followed up here, for they have been singularly unfruitful; and the difficulties which gave rise to them are part of a much larger problem which is being resolved in a different manner," p. 12.

"The immense amount of work that has been done in the last twenty or thirty years on magnetism has made it possible to trace back the phenomena observed to the atom itself. The magnetic properties of individual atoms may, to a certain extent, be deduced; and the

attempt may be made to link these up with other characteristics. Working in the opposite direction, synthesizing, a clearer idea of mass magnetic phenomena may then be obtained. Moreover, a study of the magnetic properties may throw light on many obscure features in the theory of the atom; looked at from another point of view, the quantum theory may assume new significance; and the solving of many of the problems of radiation will be helped by the key provided by a study of how radiation phenomena are affected by magnetic influences," p. 14.

"From the point of view of magnetic theory the properties of electrons moving in orbits possess particular importance, for it is clear, bearing in mind the relation between moving charges and electric currents, that such orbital electrons will behave to a certain extent as small magnets, constituting, in fact, physical magnetic 'elements.' The difficulties in connection with radiation, however, led to the invention of hypothetical magnetons, consisting of swirls of continuous electricity in the form of rings of spheres which might be supposed to give rise to magnetic fields but not to radiation. There is no experimental evidence for the existence of such magnetons; and as the radiation dilemma applies to electrons in general, the properties of these hypothetical magnetons are of little physical interest; magnetic phenomena must be explained on the basis of the experimental electrons," p. 34.

"A consideration of a grouping of magnetic molecules in isolated pairs brings out clearly the relevant determinative factors in the processes assumed to occur; but so simple a model would hardly be expected to give a complete representation of the phenomena. In particular, the possible increase in intensity after the groups are broken up until saturation occurs seems too small, while the amount of residual magnetism indicated is much less than that frequently observed. It seems necessary to suppose that the molecules can take up more than one equilibrium position; there must be more than one "line of centres" along which a molecule can set itself. Ewing in fact found that groups of four magnets gave a much closer approximation to the facts; and finally he considered continuous distribution in cubical order. In each group the molecules will normally set themselves along lines of centres, sub-groups being formed with lines of centres (and magnet axes) at right angles to each other. It may be noted that if the groups consist of pairs, or possess purely linear symmetry, each group would normally possess its saturation intensity of magnetization; whereas a group with cubical-order distribution of centres could be nonmagnetized. The point is of interest if the groups are regarded as building up constituent crystals of the ferromagnetic material.

"On the molecular magnetic theory retentivity depends on the symmetry of the molecular groupings; while coercivity depends on the strength of the molecular ties. There will thus not necessarily be any general relation between them, as is in fact observed. The theoretical retentivity for the simple groupings considered may be easily calculated. An ordinary piece of ferromagnetic material may be supposed to consist of a large number of groups, with lines of centres distributed at random. After a field is applied to produce saturation and then gradually reduced to zero, the molecular magnets in each group will be left directed along the line of centres making the smallest angle with the field, and in a sense giving a resultant moment in the field direction. Each group will retain its saturation intensity, the directions of the group moments, however, making various angles with the field; these directions will be distributed at random within a cone whose semi-angle α is determined by symmetry characteristic of the groups," p. 61.

"It may be said that in essentials, and independently of the quantum theory, little has been added to the Langevin-Weiss views. The Weiss hypothesis of an intrinsic molecular field proportional to intensity certainly enables an enormous range of facts to be co-ordinated, but the nature of the field remains unknown. Before discussing this, it may be useful to consider briefly the relation between the views of Weiss and Ewing. The control on the elementary magnets in a ferro-magnetic may be regarded, according to Weiss, as arising from an effectively homogeneous field. On Ewing's view, the control arises from the heterogeneity which results from there being strong forces in the immediate neighbourhood of the poles of the elementary magnets which are regarded as possessing finite length. Considering a linear distribution of magnets, on Ewing's view, quasi-saturation would be

approached once the magnets were deflected beyond their neutral equilibrium position; while according to Weiss, in relatively small fields, the magnet axes in an elementary crystal of the type assumed, will point either in one or the opposite direction. Ewing does attempt to account for the mechanism involved; and although the theory is inadequate, and the mechanisms so far proposed do not work, it seems premature to suppose that the whole idea is unwarranted," p. 85.

"From a magnetic point of view the transition elements possess particular interest owing to their paramagnetic characteristics. Paramagnetism occurs for other than transition elements, but not in the simple (polar) compounds where the elements enter as ions. Paramagnetism of atoms or ions is an indication of a lack of symmetry (and so of magnetic balance) of the electron orbits. In the formation of a simple compound there is a gain and loss of electrons by the constituent atoms, the outer electrons of the ion tending to assume an inert gas configuration. In NaCl, to take a simple example, the Na loses an electron, the Cl gains one; the electronic constitution of the ions will be similar to those of the inert gases Ne and Ar, which possess 'completed' configurations. These completed configurations correspond to symmetrical balanced orbital systems with no resultant magnetic moment. The ions of transition elements, on the other hand, will possess all the asymmetry of the incomplete underlying group of electrons which is being built up in them. In FeCl₃ the Fe ion contains 23 electrons; of these 18 will be distributed among the K (2), L (8), M (2), MII (2) and MIII (4) levels, as in Ar; the remaining 5 cannot form a completed symmetrical group, and the lack of balance among the electronic orbits gives the ion a resultant magnetic moment, and ionic paramagnetism occurs. The idea of associating the peculiar properties of the transition elements with the development of an underlying group of electrons was put forward by Ladenburg; it appears in its full beauty in Bohr's theory of atomic structure," p. 178.

"In the correlation of ionic and spectroscopic moments the goal has not yet been reached, but it is being rapidly approached. Much progress has been made. Amongst the wealth of detail, there is a liability to lose sight of the astounding fact that from experiments so diverse as those on susceptibilities of salts and solutions, on the magnetic deviation of atomic rays, and on the multiplet structure of spectral lines, accordant conclusions may be drawn as to the magnetic moments of atoms and parts of atoms. Details are generally being fitted into a simple and coherent design, and in the process the quantum theory, which provided the key, is itself being refined and extended," p. 232.

"From his work as a whole Oxley concluded that magnetic phenomena could not be accounted for by atoms of the Bohr type, with large electronic orbits; he inclined rather to a picture of the atom (or molecule) in which the electrons rotated in small orbits about the mean positions assigned to them in the Lewis-Langmuir static models. This seemed necessary to account for the large values of the local fields, assumed to be magnetic, between the molecules; these fields, as has been seen, being in general much larger than those which would arise from Bohr orbits. There is, however, such an enormous mass of evidence in favour of the general Bohr theory, and it accounts with such remarkable success for so many magnetic phenomena, that it is out of the question to abandon it. Moreover, the difficulty as to the magnitude of the molecular fields assumes quite a different significance as soon as the supposition is abandoned—as it must be—that the fields are purely magnetic. There are certainly many difficulties, but, in the light of the discussion which has been given of intrinsic fields in para-magnetics, it seems undoubted that for these and for diamagnetics also, a solution will eventually be found in terms of the general quantum theory," p. 280.

While the chemist will get much profit out of this book, there is a lot that he will have to skip because there is a great deal of the mathematics that is over the head of most of us.

Wilder D. Bancroft

Lehrbuch der physikalischen Chemie in elementarer Darstellung. By John Eggert. 25 × 17 cm; pp. ix + 539. Leipzig: S. Hirzel, 1926. The book is divided into three parts. The first is entitled the basis for the atomistic view-point, the chapters being the classical atomic theory and the equations of state with subheads of the elements of thermodynamics,

the elements of the kinetic theory of matter, and the elements of the quantum theory. From this one can see that the author's idea of elementary physical chemistry is primarily thermodynamics and physics, and not chemistry.

The second part deals with what some people call the physical properties of substances. The headings of the chapters are: atoms; molecules; states of aggregation (one-component, two-component, and multi-component systems).

The third part deals with chemical processes and the chapters are entitled: chemical equilibrium and the mass law; thermochemistry; electrochemistry; chemical kinetics; photochemistry.

The author is not very critical. He gives Perrin's work on the distribution of gamboge particles as though it were really accurate, p. 46; he gives the Arrhenius deduction of the osmotic pressure, p. 226, instead of the van't Hoff one; he does not worry over heats of dilution; he does not distinguish between particle size and molecular weight, p. 235; and he is very shaky on his colloid chemistry, p. 233. He says that a number of substances, such as albumin, clay, sulphides, etc., are peptized spontaneously by water (especially on washing freshly formed precipitates). As a matter of fact, these substances are peptized by adsorbed ions, hydrogen sulphide, etc. When precipitates are washed immediately after formation, what happens is that one washes out the excess electrolyte which is acting as a coagulating agent.

The difficulty raised in the paragraph on p. 74 seems uncalled for. "The positive electron is identical with the positive ion of the hydrogen atom. It possesses, like the negative electron, the charge e ; but has eighteen hundred times the mass. Its atomic weight is that of the hydrogen atom (1.008). On account of its relation to matter the positive electron is called the proton. This relation is to be accepted with some limitations. Experiment shows that just as the hydrogen atom can take up one electron at most [he means lose one], so the helium atom cannot receive more than a double charge. The doubly positively charged radical, He^+ ; contains therefore no more negative electrons [he means valence electrons] and the mass of the proton referred to one charge must have the same m value as the hydrogen ion. Actually the value calculated from He^{++} is two or practically double the value of 1.008 for He^+ . This contradiction remains when we pass to the heavier, completely discharged atomic ions (with Li^{++} for instance) and is inexplicable at present."

The reviewer is a bit sceptical about a statement on p. 162. Hydrochloric acid crystallizes at 190° absolute to a face-centered cubical lattice (probably as molecule), while below 98° absolute, another, more complicated, lattice appears. The reason for this is the motion of the particles in the lattice due to heat. At the higher temperatures, this motion is quite violent, so that the details in the field structure of the hydrochloric acid molecule become blurred and the cubical symmetry appears. At lower temperatures the movement due to heat is less, the differentiated condition of the field begins to show, and the change into the new state of equilibrium follows."

There is a very definite paragraph on steam distillation, p. 211. "If one heats water with nitrobenzene, the system boils at 99° under atmospheric pressure. The partial pressure of the water is about 74 cm and that of the nitrobenzene about 2 cm. Although the partial pressure of the nitrobenzene is only 2.64% of the total pressure, the distillate contains so large a weight percentage of nitrobenzene as to make the process advantageous, because the partial pressures are a function of the molar concentration in the vapor phase. For every mol of water distilled, 2.7% mols of nitrobenzene come over, or 3.3 g nitrobenzene per 18 g water, or 16% by weight. Distillation with steam can be used with high-boiling substances in spite of the low partial pressure, provided the molecular weight of the substance to be purified is several times as large as that of water."

There is a valuable table on p. 291, giving the chemical constants for Nernst's heat theorem for twenty-odd substances. In other pages there are tables which the reviewer was glad to see; but, considered as a whole, the book is distinctly a mediocre one.

Wilder D. Bancroft

Theoretical Metallurgy. By Reginald Scott Dean. 23 × 15 cm, pp. 246. New York: John Wiley and Sons, 1924. Price: \$3.00. In the preface the author says: "The present volume is the result of a demand for a second edition of the author's translation of Schenck's "Physical Chemistry of the Metals." When an attempt was made to revise that text, it soon became apparent that if an adequate revision were made very little of the original text would be left. The title has therefore been changed to indicate the somewhat broader field covered. . . . The book does not claim to be comprehensive; it does aim to be suggestive. . . . Some two thousand references have been given, to allow the reader to pursue the subject further."

The book is divided into two main parts, the first considering the properties of metals, the second taking up the theory underlying the various metallurgical processes. The properties are considered from the modern point of view of crystal structure as developed from X-ray analysis and are discussed under the headings: metals, metallic compounds, and metallic alloys. The metallurgical processes in turn are classified as (1) processes not involving chemical reaction and (2) processes involving chemical reaction. Under the first group of processes appear topics as thermoelectricity and thermocouples; permanent magnets; extrusion of metals; bearing metals; alloys of great hardness; welding and soldering; hardening of steel; ore flotation; and corrosion, though in many cases the treatment is necessarily very brief. Under the second class of metallurgical processes are considered the application of the Phase Rule, the Mass Law and the Theorem of LeChatelier to metal systems, together with the question of reaction velocity; the oxidation and reduction of metals; the blast furnace processes; the reaction of sulphides, phosphides, silicides and arsenides; and theory of metallic catalysts.

On page 4 the author defines the metallic state by enumerating properties which are characteristic of the metals, as follows:—

- "1. Metallic luster, or the nearly complete reflection of light from the surface.
- "2. High electrical and thermal conductivity.
- "3. Thermoelectric, thermionic, photoelectric and similar effects.
- "4. Malleability.
- "5. Monatomic condition in the vapor state and in solution in other metals.
- "6. Tenacity of gas adsorption."

On pages 47-49 metallic luster is considered. "The characteristic luster known as metallic is produced by a complete reflection of light. From the electromagnetic theory of light it follows that any substance which is a good conductor will give practically a total reflection of light. . . . Metallic luster is shown by substances which are not metallic, if for any reason they give nearly complete reflection. Thus, air bubbles under water appear metallic, as do some aniline dyes. In the latter case, however, only certain colors are completely reflected; these are the colors which correspond in frequency to the semi-bound electrons responsible for the color of the dyes. . . . Thus a piece of fuchsin paper appears like a piece of green metal."

On page 49 the author accounts for thermo-electric force as follows: "The thermo-electric force caused by the contact of two metals may be considered as the result of electron diffusion. At such a contact the electrons tend to flow from the metal with the higher electron pressure to the one with the lower. This tendency to diffuse is balanced by the electrostatic forces set up by the loss and gain of electrons.

"If a couple is then made of two junctions of different metals and these junctions held at different temperatures, the diffusion tendency will be increased at the hot end and there will be deficiency of electrons at the hot end of the metal with higher electron pressure, and the electrons will therefore flow from the cold to the hot end. In the metal with less electron pressure, the electrons will flow from the hot to the cold end.

"The electromotive force developed in the circuit will depend on the rate of diffusion. The rate of diffusion is determined by the difference of electron pressure and the difference of temperature, in a way entirely similar to the electromotive force of electrochemical diffusion cells."

During the discussion of the thermionic effect, the following interesting statement appears, p. 51: "The emission of electrons is strictly comparable to an evaporation process, and is accompanied by an absorption of heat. From a consideration of these evaporation relations it is possible to get the specific heat of electricity. This quantity, however, varies both with the temperature and the metal, being positive for mercury, copper and silver, and negative for platinum and iron."

In connection with the consideration of hardness the author observes that "with solid solution there is always an increase in hardness and correlated properties. Thompson has pointed out that the greatest increase in hardness is obtained when the two metals are of widely different atomic volume. From this he reasoned that the hardness was due to a distortion of the lattice at the points where the solute entered, this distortion interfering with the mechanical deformation. This is essentially in accord with the view of Jeffries and Archer who, however, considered that the atomic forces are increased by the greater attraction of unlike atoms. Rosenhain has placed the distortion theory on a quantitative basis. He assumes that the hardness produced by a given percentage of a second metal in solid solution is proportional to the distortion of the lattice and that the saturated solid solution represents the maximum distortion which the lattice will stand. Accordingly, the hardness produced by a given percentage of the second metal is inversely proportional to the solubility of that metal."

To one interested in colloids, the following discussion, pp. 112-114, is significant. "The formation of disperse systems in alloys is a matter of great importance, Gillett has recorded the effect of colloidal suspensions in molten brass, and the formation of plastic bronzes from copper and lead is a strictly colloid chemical process. The two metals are rendered miscible at high temperatures by means of a third substance, as sulfur or antimony and then cooled quickly so as to give the separating lead a disperse form.

"In the realm of solid alloys, disperse forms are quite common. According to Benedicks, troostite represents a colloidal distribution of iron carbide in iron and this view has been extended to cover practically all the transition products between austenite and pearlite.

"This dispersion of a newly formed solid phase in ultramicroscopic form is also exhibited by alloys of nickel and iron and of cadmium and tin, as well as for the solid solution of copper in zinc.

"A case which has been studied recently in great detail is that of duralumin, an alloy of copper and aluminum which presumably contains CuAl_2 in a state of dispersion." . . . If the facts concerning the change of crystal properties with size of grain be extrapolated to the region of colloidal dimensions, it follows that colloidal dispersions will be very much harder than aggregates of large particles of the same components. The properties of colloidal dispersions do not, however, form a transition stage between aggregates and solid solutions, since, in general, the solid solutions are softer than the highly disperse mixtures of the same components. For example, the solid solution of CuAl_2 in aluminum which is present in unaged duralumin is not so hard as the disperse system caused by the separation of the CuAl_2 as fine particles on aging. There is thus a region, the so-called critical dispersion, or zone of maximum colloidalness, which possesses the maximum hardness."

Another interesting case involving the formation of an emulsion appears on page 136. "The other type of bearing metal is known as plastic bronze; its components are usually copper and lead. These two metals are immiscible in the liquid state, and the successful manufacture of a plastic bronze depends on the solidification of a fairly homogeneous emulsion of the lead in the copper. The methods of preparation belong to a discussion of colloid chemistry. They consist essentially, however, in adding some substance, as sulfur, which increases the solubility of lead in copper at high temperatures, and then cooling suddenly so that the emulsion which forms by the separation of the lead is preserved in the solid state. A microphotograph of a typical plastic bronze is shown in Fig. 56."

The unsatisfactory state of our knowledge about soldering fluxes is evident in the following quotation, p. 150:—In soldering, the essential thing is to get a wetting of the surface with the solder. . . . "There are two forces acting on a ball of solder on a metal surface, the surface tension, p , acting tangentially to produce a spherical surface, and the

wetting effect, W , acting along the metal surface. This latter is a complex quantity and depends upon several things, particularly on the flux used. The fluxes which cause the greatest amount of spreading are zinc chloride, stannous chloride, and ammonium chloride. It is a matter of considerable importance in manufacturing to know the principle on which these fluxes act. Very little data exist in the literature on this point.

"The action is not entirely one of dissolving oxide, as a cleaned copper surface may be coated with rosin to prevent oxidation and still the spreading will not be comparable to that obtained with zinc chloride on a comparatively oxidized surface.

"The effect of surface tension cannot be an important one, since there are other salts with as high or higher surface tensions which are entirely ineffective as soldering fluxes. It may be suggested as a possibility that at the temperature of soldering the soldering fluxes give up hydrochloric acid which replaces the adsorbed air on the metal surface and is subsequently removed by the solder."

The author has succeeded in writing a very interesting book, even though the discussion is rather fragmentary in some places, and anything but clearly expressed in others, especially in the second part of the book where the phase equilibria are considered. Also the reviewer does not like the statement, p. 36, that in transition cells dealing with two metallic modifications, the modification which is out of equilibrium is the positive pole. However, the work is suggestive and in that sense amply fulfills the author's promise as stated in the preface.

T. R. Briggs

Physical and Chemical Constants and Some Mathematical Functions. By G. W. C. Kaye and T. H. Laby. Fifth edition. 24 × 16 cm; pp. 161. London: Longmans, Green and Co., 1926. The fact that 'Kaye and Laby's Tables' have passed through five editions in fifteen years, during which period they have been widely used by workers in very varied fields, gives a security against accidental errors which no new publication can afford. The task of keeping such a mass of data up to date has been effectively carried out in most sections, but those relating to surface tensions, specific heats of gases and heats of formation may be mentioned as being in some need of further revision. With regard to the subject matter, it is, of course, impossible to satisfy everyone's needs in a limited space, but it might have been expected that the present edition would contain some additional matter besides a table of isotopes. On the more chemical side, values of such quantities as chemical equilibrium constants, free energies, electrode potentials and solubility products would have been welcome. Information on these subjects is so frequently required that its provision would have greatly increased the range of usefulness of the book without necessitating any appreciable increase in its size.

No changes having been made in the arrangement of the material, the setting of the type or the binding of the book, it only remains to commend the volume as the most useful and reliable collection of physical and chemical data contained within such a conveniently small space.

H. J. T. Ellingham

STRUCTURAL COLORS IN INSECTS. II

BY CLYDE W. MASON¹

Iridescent Colors

Iridescence has for its main characteristic a change in the hue of the object exhibiting it as the angle of vision is varied; frequently iridescence is associated with marked surface lustre, which is more or less pearly or metallic. Whatever may be one's aesthetic standards, there is something peculiarly fascinating about the glinting, shifting hues shown by iridescent objects, and those which occur in nature have attracted their share of attention because this property is so markedly different from the ordinary sort of coloring. There are numerous familiar examples: certain insects, mother-of-pearl, oil films on water, tarnish on metals, diamonds and prisms, peacocks and hummingbirds, "lustre" pottery and glasses, opals, laboradorite, "Barton's buttons" and so on. One might even call "changeable" or "two-tone" silks iridescent, though in this case it is only a question of one lot of colored threads being in the proper position to reflect light while those of the other color are in an unfavorable orientation. Microscopically this is hardly iridescence, but macroscopically it satisfies the criterion.

It is commonly assumed that iridescent colors are probably of structural origin but a more definite explanation than this is necessary, and many extensive studies have been made of the different types of iridescence, and their occurrence in nature. Most works on physical optics devote a fair amount of space to the discussion of the principles underlying these phenomena, and to the criteria which may serve to identify them.

The iridescence observed in insects has been ascribed to almost every possible cause, but in most cases the problem has been attacked from one angle only. For instance, by certain quantitative optical tests a marked resemblance has been shown between the colors of certain beetles and those of certain solid dyestuffs, which give metallic reflection; however, the same tests have not been applied to film colors, to which they also bear striking resemblances. There has also been a good deal of reasoning of this sort: a grating has many lines, close together and regularly arranged, and it gives iridescent colors; certain scales of insects have many lines, close together and regularly arranged, and they show iridescent colors; therefore, the colors of the insects must be due to the grating structure. More than this is necessary, of course; it must be shown that in all observable respects the colors are identical with those obtained from gratings, and also that *they cannot be due to any other possible cause*. In the case just cited, the lines are present. They must act as a grating and they do; but the grating colors under ordinary conditions are not observable, and the colors seen are undoubtedly due to a different cause.

¹ The investigation upon which this article is based was supported by a grant to Messrs. Bancroft, Chamot and Merritt from the Heckscher Foundation for the advancement of Research established by August Heckscher at Cornell University.

In the work on structural colors of feathers, carried on at Cornell three years ago¹ it was necessary to study various types of structural colors; and tests were developed which served very positively to identify those present in feathers, namely, Tyndall blue and thin-film colors, and to exclude the other possibilities. All the "metallic" or iridescent feathers studied were found to owe their colors to thin films, but in the insect world such uniformity is hardly to be expected. The work on feathers involved a study of the different possible causes of their iridescence, and the same methods of distinguishing between these are applicable to the different cases of iridescence in insects.

Without repeating the whole discussion of the various types of structural color, for which the reader is referred to these earlier articles, the main types of iridescent insect colors will be considered, classified first with respect to their anatomical occurrence.²

Iridescent Wing Membranes

The changing colors of the wings of many dragonflies, beetles and other membranous winged insects recall the iridescence of soap bubbles, and although this is largely assumption on the part of most people, Goreau³ established their nature by a very sound and logical study.

Obviously, the colors are structural, for they are observable in wings which are wholly unpigmented, as well as in pigmented wings after bleaching. The variety of coloring and its intimate mingling in such small area also make considerable demands upon any theory of their pigmental origin, while the undiminished iridescence in specimens bleached to colorless transparency is radically different from the selective metallic reflection (surface color) of strongly absorbing substances such as dyestuffs. They appear with full brilliancy in highly diffuse light, and are seen from any azimuth, along the line of direct reflection from the wing surface, so they cannot be due to structure of the nature of diffraction, gratings or prisms, all of which require sensibly unilateral illumination, and show their coloring in directions out of the line of the direct beam, and in one plane only (unless an infinite number of crossed gratings or prisms be postulated). No indication of any such structures is observable by microscopic examination.

Other special cases of diffraction phenomena are also eliminated by the above simple observations, for there is no "scattering" of light other than that due to the "pebbled" surface of the wing membrane, nor is there any evidence of haloes or coronas from any fine granular structure.

A more detailed study of the specimens in questions throws additional light upon the nature of these colors. The common house-fly affords an example. Its unpigmented wings exhibit highly variegated colorings, mostly reds and greens, when examined closely with the naked eye or with a low-

¹ Mason: *J. Phys. Chem.*, 27, 201, 401 (1923).

² The insects studied in this paper were furnished through the kindness of Dr. W. T. M. Forbes, of the Department of Entomology at Cornell. The writer is also indebted to Dr. Forbes for many helpful suggestions during the progress of the investigation.

³ *Ann. Soc. Ent. fr.*, (2) 1, 201 (1843).

power magnifier. These are mingled together wholly at random except near the edges of the wings where they appear in zones. The colors are seen very clearly by reflected light, when observed along the line of direct reflection; and any given point on the surface of the wing changes color as the angle of vision is increased. This change may be from red to green, or *vice versa*; the zones of color near the edge of the wing appear to move outward as the line of vision approaches grazing incidence.

"The "pebbled" surface of the wing membrane prevents the observation of any definite polarization effects by reflected light; such a surface has of course no definite "polarizing angle" and one sees little more by using an analysing nicol prism than without it.

The above surface structure also prevents the effective application of pressure, for such severe tangential strains must result when attempt is made to flatten the "embossed" surface and to compress the membrane that disruption of the structure is likely to result. However, there seems to be a slight shift in the hue of the reflection color, but this is not to be observed with certainty.

When examined by transmitted light the membrane shows only very pale tints which are complementary to those of the same areas seen by reflection.

Swelling agents such as NH_4OH , water vapor, or phenol vapor alter the hues markedly, causing reds to change to greens, and *vice-versa*; these color changes are reversed on the removal of the swelling agent. Immersion in liquid of $n = 1.5$ destroys the color, which is restored by washing and drying.

The iridescent wing membranes of many common beetles show much the same optical behavior as those of the housefly, but present some significant differences. They are pigmented a neutral brown; their reflections resemble the "temper colors" of steel, both in hue and in metallic lustre, and range from blue through purple to yellowish brown nearer the edges and tips of the wings. The changes with increasing incidence are marked, and take place in the order just mentioned; on swelling, the change is in the reverse direction. Bleaching does not alter the hue, though the lustre is less in the bleached specimen.

Splitting the lamellae of the wing apart does not destroy the iridescence; the original colors are seen only on the outer surfaces. The inner surfaces may show different iridescent colorings.

Collodion impressions of either surface show no iridescence, and no structure but the fine wrinkles and stubby hairs of the wing membrane.

Immersion of the wing in liquids of index of refraction *ca.* 1.5 does not result in complete destruction of the iridescence, though the brilliancy of the coloring is very markedly decreased; penetration of the wing of liquids which fill the space between its upper and lower lamellae does not destroy the iridescence.¹

In addition to the above-mentioned examples, a number of other insects were examined with respect to the same properties, *Tylope laricis*, *Mesothemis*

¹ Goreau thought that the interlamellar air space was the color-producing film.

simplicicollis, *Enallagmae*, *Dolichopus canaliculatus*, as well as the wings of several beetles; these all show substantially the same behavior as regards their iridescence, color change with swelling, sequence of colors on the wing, and absence of any but a neutral pigment. The disappearance of color on immersion seems to be peculiar to the wings of the housefly, however.

Nature of Iridescent Coloring of Wing Membranes

Since pigment coloring and diffraction phenomena as causes of the iridescence are eliminated, the most obvious explanation is on the basis of the colors of thin films, and the behavior described above is in good agreement with this very common assumption. Iridescence is the most striking property of thin-film colors, and their definite sequence of hues (Newton's series) is almost as well known: As the thickness of the film in question increases, a succession of colors occurs which is characteristic to one who is familiar with this series. The series is *not* a spectrum, and the color changes are not to be described in terms of wave-length, but rather as of higher or lower "order," the latter corresponding to the thinner films. Increasing the angle of incidence is equivalent to thinning the film¹ and the colors change accordingly. Swelling or compression of the color producing films alter their thickness, and consequently their color. The very pale tints observed by transmitted light are due to the large admixture of white transmitted light. Against a dark background the reflection colors are complimentary to those transmitted, and of considerable saturation and brilliancy.

With respect to all the above properties, the colors of iridescent wing membranes correspond closely with those of thin films; however, certain discrepancies must be considered before their identity can be called established. If a thin color-producing film is brought in contact with a medium of index of refraction near its own, it should show a very marked diminution of its color, with complete disappearance if the index of refraction is matched exactly. In the case of the common housefly this is readily observed, but with the other wings examined only a decrease in the intensity of the color takes place, even when the wing membrane is immersed in liquid of refractive index near that of chitin. This same behavior is found in the case of iridescent feathers, and is best explained on the assumption that the color is produced by multiple thin films, only the outer one of which would have its action affected by contact with a medium of similar index of refraction. We ordinarily think that a thin film must have a markedly different index of refraction from the surrounding medium if it is to produce color and appear metallic. However, a single thin film of xylene ($n = 1.49$) on glass ($n = 1.52$) shows Newton's series of colors distinctly as it evaporates. The brilliantly lustrous and iridescent flakes that fall from the surface of ancient Roman or Egyptian glass consist of thin laminae (of SiO_2 ?); they offer a convenient "model" for the study of multiple films. When dry, their reflection is highly metallic and their transmission-colors are much more saturated than those of a single thin film. If one of these flakes is immersed in liquid, so that the voids between the laminae are filled,

¹ C. V. Boys: "Soap Bubbles," 148, 151 (1912).

its color and lustre are somewhat diminished; but the index of refraction of the immersion medium must be almost identical with that of the films if all reflection color and lustre are to be destroyed. The iridescent crystals of potassium chlorate studied by Stokes¹ and the fiery patches in the opal are other examples of multiple films in optical contact with a solid medium having nearly the same index of refraction as their own.

The effectiveness of such a color-producing system depends on the difference in indices of refraction and on the number of films; both of these factors may be relatively small without serious loss of saturation or lustre.

The saturation and brilliancy of the colors of even the brightest iridescent wing membranes are closely rivalled by those of artificial thin films such as can be made by allowing a drop of gold size to spread over water. Such a film, after it hardens, may be picked up on a piece of wet paper (preferably gray or black, to give a dark background) and the distribution and sequence of its hues, compared with those of the insects, show a most striking similarity. As for the more or less metallic lustre exhibited by the iridescent wing membranes, this is no more marked than that shown by artificial thin films. If multiple films are present in the wing membrane they might be expected to cause somewhat greater saturation and lustre than a single thin film, but this is opposed by the irregularity and "pebbled" character of the membrane and by its lack of perfect transparency.

Biedermann's explanation of the iridescent colorings of wing membranes as being due to an air film between the two lamellae of the wing² is not adequate, although he has recognized the nature of the colors by means of the criteria mentioned above. The thickness of the air film in the interior of the wing is many times greater than that corresponding to the colors exhibited; it may be filled with liquids, or it may be closed or opened by pressure or splitting without altering the colors.

The highly intricate mingling of colors in a small area of a continuous membrane would involve an extremely complicated pigment distribution, if such were possible, but is readily accounted for by slight variations in the thickness of the color producing film. This is confirmed by the fact that these variations of color do correspond to relatively gradual variations in thickness rather than being a mosaic of sharply outlined areas of different colors, and moreover the colors adjacent on the membrane are those adjacent in Newton's series. This is particularly striking near the edge or tip of the wing, where a definite sequence of color zones, (first three "orders" of Newton's series) corresponding to a gradual decrease in thickness, is observed. Such a structural condition is just what one would expect, and conversely, where veins extend out to the edge of the wing, the color zones are altered in a manner that indicates increased thickness near the vein.

Swelling with water or other reagents causes the zones of color to shift toward the edge of the wing, without other alteration of their hues or se-

¹ Wood: "Physical Optics," 161 (1911).

² Handbuch der vergl. Physiol. 3, I, 2, 1657 (1914).

quence; on drying, the color zones shift back again to their original positions.

Microscopic demonstration of the actual structure is hardly to be hoped for since the thickness of the films as calculated (*ca.* 0.2μ) must be practically at the limit of resolution, and this limit may be reached only with good "contrasty" objects, suitably prepared. In this case undistorted microtome sections of the same order of thickness as the films themselves, together with highly selective staining of the material of the films would be necessary in order to avoid the possibility of spurious diffraction images. Optical tests are certainly more reliable than histological study, in this instance, and they point to a structure composed of a number (say three to ten) of films of materials of different index of refraction (possibly two varieties of chitin) in optical contact and forming a non-permeable tissue which constitutes the two lamellae of the wing. People were right when they guessed that filmy wings must have thin-film colors.

Iridescent Scales

The explanation of the iridescence of butterfly and beetle scales not being so obvious as in the case of wing membranes, almost every writer on insect colors has had a try at it. The presence of striations has suggested a diffraction grating, and this is popularly assumed to be the cause of the color, although most of the later investigators have not fallen into this error. The people who use the terms "diffraction", "refraction", "dispersion", and "interference" indiscriminately and with reference to either gratings or thin films, who speak of "prismatic" colors when they mean iridescent ones, and who believe that "structural color" tells the whole story, are the ones who have perpetuated this untenable opinion. Hagen¹, Biedermann², Onslow,³ Süffert,⁴ Mallock,⁵ and others, have pointed out that most scales, whether iridescent or not, are distinctly striated, and these writers have offered various other objections to a diffraction theory. Walter⁶ emphasizes the fact that the principal striations are lengthwise yet the colors may be seen with the light falling either lengthwise or crosswise of them. He also points out that a grating requires sensibly unidirectional light for the production of colors, while the scales are fully colored in thoroughly diffuse light. Hodgkinson⁷ cites the fact that grating colors are always seen out of the path of the directly reflected or transmitted beam, while the scales show specular reflection, and color in the path of the transmitted light.

All these properties of gratings have been known to physicists for many years, while those of the insect scales can readily be tested by anyone, yet the serious discrepancies given above have not been accepted as conclusive evidence against the diffraction grating explanation of iridescence on insect

⁷ "Manchester Memoirs," 2, (4) (1889).

scales. Dimmock,¹ Kellogg,² and Mayer³ have been content with such an explanation, and Michelson⁴ has postulated a "saw-tooth grating" to reconcile the properties of certain iridescent scales (*Entimus imperialis*) with those of diffraction gratings. Such an unsymmetrical structure is hardly consistent with the highly symmetrical properties of the scales in question, and in addition is open to all the objections given above. It will be dealt with further when the insect studied is discussed.

It is possible to illuminate any scale having reasonably regular striations so that it can act as a grating,⁵ but this is entirely independent of whether the scale is iridescent or not as ordinarily seen, and is hardly observable without the aid of the microscope. Latham⁶ pointed this out many years ago.

The arrangement of scales on butterflies wings is ordinarily not suitable for the demonstration of diffraction colors, on account of the lack of perfect parallelism of the striae and of the scales. In the case of the "Pearl Morpho" there appears to be some chance of observing diffraction colors under natural conditions though only when the direct rays of the sun fall through the wing and are observed from a point somewhat to one side of their path.⁷ The colors seen when the wing is studied with illumination corresponding to this are faint, reminding one of those of mother-of-pearl (another case of diffraction colors in nature), and are very non-uniform.⁸ They are barely perceptible in the more pigmented Morphos even under the most favorable conditions, and the yellow transmission color seen in the field by some observers is mainly due to pigment and to the complement of the blue reflection.

Dimmock, Onslow and others have isolated the diffraction effect from the other color producing factors present, by making impressions of the striae of the scales in soft collodion and these "replica gratings" may be made "with most Lepidoptera, whether iridescent or not. . . . That all insects, the impressions of whose scales give spectra, do not themselves show iridescence, makes it doubtful whether diffraction is ever a main source of color, especially as it was found that the brilliant scales of *Morpho Cypris*, Westw., and others with the same structure, gave an almost flat impression."⁹

³ Proc. Boston Soc. Nat. Hist., 27, 243 (1896-7).

⁴ Phil. Mag., (6) 21, 564 (1911).

⁵ A special case of purely microscopic diffraction color is exhibited by many unpigmented, boldly striated scales. The color by transmitted light is a fairly deep blue if observed under the proper conditions, namely: with the aperture of the illuminating beam from the condenser bearing such a relationship to the aperture of the objective that the diffraction spectra seen at the back of the objective are well defined, the longer wave lengths (the most diffracted) being outside the cone of rays grasped by the objective. This phenomenon is fairly commonly noted in microscopic studies of fine structures and a fuller treatment of it will be presented in a later paper.

⁶ Proc. Manchester Lit. and Phil. Soc. 3, 198 (1864).

⁷ Mallock (*loc. cit.*) has called attention to this.

⁸ The angle at which this spectrum is diffracted can be roughly measured and the "grating space" calculated from it, with a fair approximation to the interval between the striae as measured microscopically.

⁹ Onslow: *loc. cit.* p. 11.

Selective reflection (surface color) has been thought to be the cause of iridescence in insects. Walter,¹ who saw "*Oberflächenfarben*" in almost every case of iridescence in nature, failed to reconcile this hypothesis with many of the well-known properties of the objects to which he applied it. Iridescent scales have many such points of difference: sensitiveness to pressure or crushing,² resistance to bleaching or extraction,³ loss of color or permeation with liquids and restoration on drying,⁴ transmission color much less saturated than reflection color,⁵ highly complicated mingling of hues,⁶ very marked change of reflection and transmission colors with angle of incidence.⁷ These discrepancies parallel those emphasized by the present writer in eliminating selective reflection from the possible causes of iridescence in feathers. Moreover, it must be borne in mind that the polarization effects and metallic lustre,⁸ and the brilliant colors⁹ exhibited by selectively reflecting substances are very similar to those of thin films. Süffert,¹⁰ is an admirably scientific study, has assembled the properties of the various types of color possible in iridescent butterfly scales, and concludes very positively against the "surface color" theory. If it were only supported by Walter, it would probably have ceased to trouble people; but Michelson's paper¹¹ gave it a new lease of life.

He starts out with the statement that interference colors are "so rare and so readily distinguished from the true metallic [surface] colors that they may be most conveniently treated as exceptions after the subject of surface color has been considered," yet the chief characteristics by which metallic reflexion may be distinguished are as follows:

"1—The brightness of the reflected light is always a large fraction of the incident light, varying from 50 percent to nearly 100 percent.

"2—The absorption is so intense that metal films are quite opaque even when their thickness is less than a thousandth of a millimeter.

"3—If the absorption varies with color, that color which is most copiously transmitted will be part of the incident white light which is least reflected—so that the transmitted light is complementary to the reflected.

"4—The change of color of the reflected light . . . follows the invariable rule that the color always approaches the violet end of the spectrum as the incidence increases."

As Onslow has shown by quantitative measurements, and as anyone may observe for himself in a qualitative way, thin films, especially multiple films satisfy the first criterion. Michelson has admitted that the natural iridescent

¹⁰ *loc. cit.*

¹¹ *loc. cit.*

colors "are far more vivid than any of the reflexion hues of aniline dyes, or any other case of 'surface color' yet discovered." Rayleigh has taken issue with him on the second count, pointing out that the transmission colors of the insect scales are very much less saturated than those of dyestuffs, while the reverse is true of the respective reflection colors. In the single instance where Michelson tried to penetrate an insect scale by liquid he notes that the iridescence was completely destroyed if the index of refraction was between 1.5 and 1.6, and admits that selective reflection is ruled out in this particular case. As many investigators have noted, this loss of color on penetration appears to be without exception in the case of the iridescent insect scales. Rayleigh also points out that the third criterion is only roughly correct, and it is well known that more than one type of structural color shows complementary reflection and transmission. He also emphasizes that "with ordinary unpolarized light the surface colors appear to change too little" with changing incidence, and concludes that "Michelson's four tests are as well if not better borne by an interference theory." The present Lord Rayleigh¹ and Mason² have pointed out exceptions to the statement regarding the invariable change toward violet with increasing incidence.

Michelson's quantitative study of the "phase differences" and "amplitude ratios" of the elliptically polarized light reflected from dyestuffs and from "metallic" insects and feathers shows fair agreement. But the surfaces of the latter specimens are highly complex, as he admits, and the measurements have not been made on any types of structural color for comparison, though thin films are known to polarize light elliptically, and to behave similarly to surface colors with polarized light,³ and since his "metallic" feathers turned out to have thin-film colors, this phase of the evidence can not be taken too seriously. The present Lord Rayleigh has been able, by means of spectrometric examinations, to obtain data showing that some of the beetles which were Michelson's best examples of surface color exhibit optical behavior corresponding to that of multiple thin films. Merritt⁴ has made some more recent spectrophotometric studies on feathers and butterfly scales which show good agreement with the properties of thin films. Keeley⁵ came to a similar conclusion as a result of his work with the microspectroscope.

As far as qualitative tests go the evidence is certainly against the "selective reflection" theory, and the odds appear to be more than even on the quantitative side as well.

The various other theories which have been advanced to explain the iridescence of insect scales are of minor importance. Resonance has been suggested by Wood.⁶ Kossonogoff⁷ assumes that all the colors of *Lepidoptera* are due

¹ Proc. Roy. Soc., 103A, 233 (1923).

⁷ Physik. Z., 4, 208, 258 (1903).

to the resonating properties of fine pigment granules in their scales and Chirvinski¹ elaborates this theory. Such an all-inclusive explanation leaves us no better off than before, while resonance of the sort Wood observed with his granular metal films is subject to the same objections as selective reflection, of which it is a special case.

Studies of Typical Iridescent Scales

It will be seen from the studies of typical specimens which follow that their properties are, as indicated above, markedly at variance with those of diffraction or selective reflection colors. Positive evidence in favor of another explanation will be presented later.

The specimens were first examined with the naked eye, both with diffuse and unidirectional light at varying angles of incidence and falling crosswise and lengthwise of the scales. The inclination, curvature, and arrangement of the scales on the insect were observed with a Greenough-type binocular microscope to which was attached an orienting device so that a variety of relative positions of the scales, wing, illumination and observer were possible. Scales were removed from the specimen by scraping or by picking up on a cover glass slightly sticky with a film of balsam or glucose. This afforded an easy method of observing several scales at one time, and of studying their under surfaces. The reflecting properties of the scales were observed under inclined illumination, and also by means of a vertical illuminator fitted with a movable reflector so that the incidence of the illuminating beam could be varied within the angular cone of the objective. An iris diaphragm stop in the objective enabled its aperture to be reduced so that the light was almost wholly vertical rather than convergent. Reflection, transmission, and polarization at various orientations could be observed systematically by means of a Fuess petrographic microscope with theodolite stage.

For detailed study of the fine structures of the scales a number of different objectives, including those of 1.40 N.A. were available, and it was found that a fairly adequate idea of the cross-section and the interior of the scales could be formed by careful focussing of a lens of the appropriate aperture ("optical sectioning") and by proper manipulation of the condensor to furnish axial or oblique illumination. The interpretation of appearances by such a procedure was substantially in agreement with that obtained from study of the sections, in cases where these were available for comparison. In this phase of the investigation Onslow's observations can hardly be surpassed; his paper gives excellent figures of sections of a large number of scales, but, as Süffert says, a clear understanding of the general structure of the scale should precede a study of its cross-section. The latter is useful mainly for relatively large details and as a confirmation; the minute structures may often be revealed quite as usefully in torn or crumpled scales. Fracture, behavior under compression, and the process of slow permeation by viscous liquids are of great value in forming a concept of the object which is under examination.

¹ Russ. Ent. Rev., 15, 513 (1915).

Since the structures concerned in the production of color are practically at the limit of resolution, even under favorable conditions, it is obvious that optical tests are likely to be more significant in establishing the nature of the observed phenomena. The conclusions drawn from such tests should of course be compatible with any structural conditions known to be present.

The behavior of iridescent scales in response to swelling agents is noteworthy, and is best brought out by exposure to phenol vapor,¹ since this does, not wet the scale, and is readily removed by exposure to the air. Ammonia water, alcohol, and many other liquids have considerable swelling action also.

A series of practically colorless liquids, varying in index of refraction from 1.33 to 1.8, enables the scale to be surrounded or permeated by media of a wide range of refractivity. Liquids of different degrees of volatility (water, alcohol, benzene, xylene, etc) are useful in the study of the surface and internal structure of the scale as these are exposed by the evaporation of the liquid in which it has been immersed.

Bleaching, where necessary to eliminate the effect of pigment or to establish its absence, is best carried out with concentrated hydrogen peroxide (10-30%).

Urania and Similar Scales

Urania (Chrysiridia) ripheus is perhaps the most striking of all the iridescent scale-bearing insects, both because of its brilliancy and its variegated hues. The fore wings are blue green, changing to violet at grazing incidence, and the hind wings are a bronze green shading into reddish purple. The under surface of the hind wings presents a number of hues. At their roots they are brilliant bluish green, and vary in a distance of 5 mm. through blue, purple, and red to orange. The main area of the under side of the hind wing is greenish brass-yellow, in the center of this space the color varies through orange to red. The above colors are described as seen at normal incidence. Their distribution most closely resembles the zones of color seen when oil is spilled on wet asphalt pavement.

Structural Features. The iridescent scales are square-ended, strongly convex about their transverse axis at the outer extremity, so that on the wing the surfaces exposed are highly curved. Detailed study of scales from the different colored areas reveals no observable structural difference. Separate scales are longitudinally striated on their upper surface, the striae being really thin vanes, separated by spaces four or five times their thickness, the under surface is practically smooth. Transmitted light reveals, in addition to the longitudinal striations, a faint irregular tracing which appears to be inside the scale, and is probably the residue of the scale contents. Broken or crumpled scales permit the vaned structure to be recognized as part of the upper lamina of the scale, the lower lamina appears thicker (ca. 2μ) and in close contact with the upper one. Edges of torn fragments indicate a cleavage in the plane of the scale. The individual lamellae are not sharply defined, but the broken

¹ Wilson [(Psyche. No. 75 (1880)] noted that an insect packed in a box with phenol on cotton, and sent to be painted had its color changed from rich purple to green; fortunately for the picture a short exposure to the air was sufficient to restore the original hue.

edge resembles a torn group of sheets of paper, and buckling of the scale may cause them to separate somewhat. This lamellar structure is undoubtedly existent, though composed of films too thin to be visible even in Onslow's excellent sections. There are probably between five and ten lamellae present. Accurate observation of their individual thickness and that of the space between them is excluded by the limitations of resolving power of the microscope and the technique of sectioning.

Optical Features. As they lie on the wing, the scales show high reflecting power, through a considerable angle, but examination under the Greenough binocular microscope shows that the reflection is strictly specular, and the convex surface of the scale permits some part to be in position to reflect through considerable variation in the inclination of the wing. The reflecting power is high, and the lustre is metallic, apparently nearly as bright as polished copper in the case of the red scales. The reflection comes from spaces between the vanes. Lustre and specularity of reflection are even more marked on the smooth under surface of the scale. Torn or split scales show that the reflections come from the lower lamina, and the very thin upper lamina with its vanes acts only as a screen thru which these reflections are observed. Under fairly diffuse illumination the reflection color of the scale is not uniform, but varies markedly from center to tip. This is due to the different inclination of these different portions of its surface, for when the scale is flattened, or when the angle of incidence is actually the same, the color is correspondingly uniform. The uniformity is not perfect, for slight local variations are apparent. These blend into the adjacent colors, and in no case are there marked differences in hue. The reflection colors are highly saturated and are localized in the lower lamina.

The transmission color is much less saturated and is tinged with the faint yellowish pigmentation of the scale. The hue varies from center to tip just as does the reflection color, and this variation is eliminated by flattening the scale or by tilting it so that the different portions of its surface are each successively observed with axial light. The transmission colors are complementary to the reflection colors, as shown by combined reflected and transmitted illumination.

As the angle of incidence is increased the hues of the reflection colors change very strikingly, this is much more marked in the individual scale than on the wing because of the multiple convex character of the latter, which permits a wide range in the angle of incidence and a consequent lessening of the purity of the colors and of the sharpness of their changes. The sequences from normal to grazing incidence are as follows:

green → blue → purple,
blue → purple → red → orange,
reddish purple → orange → yellow green.

Some scales, violet at normal incidence, go through reddish purple, copper red and orange yellow to greenish yellow, with increasing angle of incidence. The above changes in the reflection colors are accompanied by corresponding

changes in their complementary transmission colors. On the wing the joint effect of these color changes results in a *shifting* of the color zones. The bands of blue, purple, red, and orange move to the adjacent portion of the wing, while maintaining the same zonal distribution. This shift of location is toward the portion of the wing blue at normal incidence, and is due to each of the colors changing to ones following it in the above series.

When the change in hue of the reflection color is analyzed by a nicol prism, one notes that if the plane of vibration of the nicol is perpendicular to the plane of incidence of the light the color phenomena are practically the same as without it. If the plane of vibration of the nicol is parallel to the plane of incidence the reflection is practically destroyed at an angle of about 60° to the normal, and, at greater incidence than this, the color is complementary to that seen with the nicol in the perpendicular position or with it removed completely. If a " $\frac{1}{4}$ undulation" mica plate is inserted, the plane of the nicol being parallel to the plane of incidence, the color undergoes a complementary change.

Between crossed nicols the scales are seen to be anisotropic, with extinction parallel to their longitudinal striae. This is purely structural anisotropy, for it is destroyed when the scale is rendered optically homogeneous by permeation by a liquid of the same refractive index as chitin. Any reflecting or refracting surface tends to depolarize light; multiple surfaces, such as the grooves of a deeply ruled diffraction grating exhibit this effect and the parallel ridges of the scale undoubtedly act in a similar manner.¹ The anisotropy is not sufficient to interfere with the observation of the elliptical polarization of the reflected light described above, for this may be observed with the scale in any azimuth, and depends only on the angle of incidence.

The distribution of colors on the individual scale, as mentioned above, is not perfectly uniform; a given hue such as red may show variations toward adjacent colors, such as purple or orange. These variations are gradual, though they may take place in a distance of only a few microns. The complementary color shows similar variations, though these are much less marked because of its low saturation.

Pressure applied to a scale causes a very marked change in its hue. This may be carried out under objectives of fairly short working distance by wedging a spear-pointed dissecting needle between the mount of the objective and the cover glass. Transmitted or reflected light may be used for observation. Very slight pressure is sufficient to alter the color to an adjacent one, and increased pressure brings about a succession of colors similar to the sequence seen with increasing angle of incidence. Extreme compression destroys all but the faint yellow pigment color. Unless the scale is actually disrupted the original color is restored on removal of the pressure, particularly if the atmosphere is moist.

Under the microscope the effect of pressure may be seen summarized on a single scale which has been bruised locally by a dissecting needle or com-

¹ Ambrohn [(Kolloid-Z., 6, 222 (1910)] has termed this phenomenon "rod double-refraction."

pressed only at one end. The whole series of reflection and the transmission colors is present in a space of a few microns. Yellow-green scales are altered through green and blue to purple by reflected light (more severe pressure disrupts the scale and destroys the color); the transmission color goes through purple and red to orange, and is finally lost in the yellow of the pigment. Red-purple scales go through red and orange to yellow, or yellow green, the complementary transmission color, bluish-green, is lost with moderate pressure and only the yellow of the pigment is seen.

Swelling the scales is carried out by exposure to phenol vapor, ammonia or even water vapor. Here again the color changes very strikingly and in a sequence the reverse of that caused by compression. The original color is restored on exposure to the air.

Penetration by liquids affords the most convincing proof of the structural nature of the colors of the scales, for if the liquid is of index of refraction substantially the same as that of the scale (as determined by the Becke test)¹ the reflection color is completely destroyed, and only the transmission color of the pale yellow pigment remains. The original color is perfectly restored on removal of the penetrating liquid. If the index of refraction of the chitin is not perfectly matched, the loss of color is not complete, though with liquids of n between 1.5 and 1.6 it is very nearly so. With liquids of index of refraction widely different from that of chitin, the intensity of the reflection and transmission colors is decreased, and in addition their hues are altered. This alteration results in green scales becoming red, and may be due to the swelling action of the liquid, (which would cause a change of this nature) or to the replacement of the air in the voids of the scale by a medium of higher refractive index. Certainly the former plays a considerable part in this color change for one notes under the microscope that the *saturation* of the color may be restored by replacement of the liquid by air, but the original *hue* is regained only after a few seconds further drying to remove the swelling liquid in the scale tissues themselves.

The progress of the penetrating liquid may be followed under the microscope, if liquids of high viscosity (balsam or glucose) are used, and it is seen that the liquid enters most readily at breaks in the scale, spreading through it independently of the striations or other markings. If only the outside of the scale is wetted no loss in color results.

When the permeating liquid is allowed to dry out slowly the varnished surface is first exposed, and at this stage the scale is still colorless. On further drying, flashes of color appear over areas in various parts of the scale, and these colors apparently become more saturated with succeeding overlapping flashes until finally the original saturation of color is restored. This spreading of the color throughout the scale is independent of its striae, and is similar in appearance from either surface.

The optical properties of other *Uranidae* are closely similar to those of *U. ripheus*, with minor differences as regards the hues present. Bronze-green,

¹ Johannsen: "Manual of Petrographic Methods," 271, (1918).

changing to blue or purple at grazing incidence and to copper red on swelling, is their most prevalent color. The changes on compression are very striking, on a single scale one may see absence of color where the pressure has been most severe, and transmission colors of yellow, orange, red, purple and blue in order outward from this point, with a corresponding complementary series of reflection colors. The parallelism between the variation of both reflection and transmission colors with pressure and with increasing incidence is highly perfect.¹

Ino statices has iridescent scales of the same general type as those of the *Uranidae*, but differing from them in certain structural features. Their bronze-green color is localized in the upper lamina of the scales, and shows specular reflections, change with pressure, swelling, or varying incidence. However, the longitudinal corrugations of the upper lamina, instead of being fairly smooth ridges, are studded with rows of raised bosses. The sides as well as the tops of these reflect specularly and evidently this is simply a special case of a very highly "embossed" upper lamina, similar in other respects to that of the scales just described.

Papilio peranthus shows the converse of the above structure, with longitudinal ridges, unevenly spaced cross ridges connecting these, and depressions in the space between these raised structures. Siffert aptly compares the surface to that of a waffle. The reflection is specular from all parts of this embossed surface, just as in *Ino statices*. The under surface of the scales shows the reverse of these depressions as elevations, though the reflection is hardly as brilliant.

Many iridescent butterflies exhibit optical properties very similar to those of the *Uranidae*. The scales of *Papilio philenor* contain a dark pigment localized in their upper lamina, which is relatively thick, with shallow longitudinal ribbing. They show the color changes with inclination, pressure, swelling and penetration as do the scales of the *Uranidae*, but the pigmentation suppresses the clearness of these phenomena somewhat, particularly on the upper surface of the wing. The lower lamina is iridescent, independent of the upper one. Because of its less pigmentation and unstriated surface it is rather more brilliant. A lamellar structure is indicated by the character of torn and crumpled edges, and the lamellae of the upper lamina follow the ridges of its surface. *Papilio asterias* exhibits much less perfect color producing scales, with hardly perceptible iridescence or metallic lustre. It is more heavily pigmented, and the striated and cross-marked upper lamina constitutes a screen which practically conceals the iridescence of the lower lamina.²

Papilio neophilus olivencius has a similar mesh structure on the upper surface of the scales, which gives them a matte lustre. The seat of the

¹ The foregoing observations are very similar to those made by Siffert, who considers the scales of *Uranidae* as a type example. The colored plates of his paper represent the above variations in hue very vividly.

² Such a structure is similar to that found in many scales not thought of as iridescent, in which the relatively opaque and heavily sculptured upper lamina conceals the lightly pigmented, highly iridescent lower lamina. The under side of the black scales of *Urania ripheus* shows brilliant iridescence. Indeed, iridescent lower laminae are very common in the scales of moths and butterflies, whether the scales are iridescent or not as seen on the insect.

iridescence is beneath this layer, and is very brilliant from the under side of the scale. The scales of *P. nireus* and *P. zalmoxis* are essentially similar.

Callimorpha dominula is much the same as the preceding specimens, having a heavily pigmented, non-iridescent upper lamina, which masks most of the iridescence of the thin, unpigmented lower membrane.

Lycaena icarus, a common European butterfly, is a bright lavender; the wing appears light gray at grazing incidence. The inclination of the scales on the wing is partly the cause of this, but another factor is more important.

The almost complete loss of iridescent color at large angles of incidence is due chiefly to the character of the upper lamella of the scales. This is longitudinally striated, the striae being connected at short intervals by a fine cross-structure, making a mesh pattern which is relatively thick. The openings of this mesh are large enough so that the iridescence of the lower lamella is visible through them at small angles of incidence, but as the angle approaches grazing, the iridescence is hidden behind the edges of this boldly sculptured structure. As far as can be observed under these circumstances, the optical properties of the scales parallel those of the specimens already described. Pressure causes a marked alteration of the color of the scales, but since they are very thin, Newton's rings may be seen between the slide and the cover glass in their vicinity, and these colors are likely to be confusing. Very sudden release of the pressure destroys the Newton's rings before the scale has time to recover its original hue.

The lavender color is completely destroyed on penetrating with a liquid of $n = 1.5 - 1.6$ and, on drying out, an interesting sequence of changes is noted. When the outer surface of the scale emerges from the liquid, its raised striations produce a blue transmission color, as seen with an objective and condensor of the proper aperture.¹ Then the liquid in the underlying tissues is gradually replaced by air, and the yellow transmission and lavender reflection colors are restored. The scales of *Lycaena corydon* are substantially the same as those of *L. icarus*, but more closely striated and less lustrous. *Basilarchia astyanax* has scales similar in structure to those of the *Lycaenae*, with a "mesh" upper structure and an iridescent lower lamina, the colors of which are ordinarily seen through the openings of the mesh. *Cercyonis alope* is similar, but much more pigmented, with iridescence visible only under brilliant illumination.

The genus *Anaea* contains some good examples of iridescence similar to that of the *Urania* moths. *A-morvus* is particularly noteworthy for the great change which its colors undergo on exposure to phenol vapor. Light greenish blue at first, it changes through bronze green, orange and copper red, to purple with maximum swelling, and passes through this series in the reverse direction in a few minutes when exposed to the air. The same reversed sequence is noted as the angle of incidence goes toward grazing, though this is not so easily observable on account of the inclination of the scales on the wing, and because the upper lamina possesses a "mesh" structure similar to that of *Lycaenae*.

¹ See page 327, footnote 5.

Helicopsis cupido and *Argynnis* ("Silverspot") are examples of another sort of scale color, of the same type as that of *Uranidae*. Their scales are pigmentless, and give a general effect of white on the wing, with bright silvery lustre microscopically. Rather pale iridescent colorings are observable by reflected light, and less saturated, complementary ones by transmitted light. The coloring is not uniform, and the various hues blend into each other giving an appearance much like mother-of-pearl. The behavior with pressure or when penetrated by liquids is closely similar to that shown by the insects described in the preceding studies. The specularity of reflection is another point of resemblance.

Cocytia durvilli has iridescent body and leg scales which are of the same general type as the others just described. Their elongated character adds to the satiny lustre as seen on the insect.

Of more primitive forms, *Eriocrania* (*purpurella*?) shows scales having a very simple structure, consisting apparently of a simple basal membrane bearing longitudinal ridges or vanes. This behaves as if it were a single thin film with no interior air space. The reflection color (purplish to orange) is relatively faint, and is lost if either the upper or lower surface of the scale is in contact with liquid.

The foregoing specimens have all been essentially similar as regards the color-producing portion of the scale, and their differences lie chiefly in the various means by which the action of this structure is modified by other portions of the scale. The seat of the iridescence, in the above cases, may be in either lamina of the scale; the upper lamina may vary from a simple vaned film overlying the reflecting structure to a pigmented mesh structure in high relief. The reflecting plane is parallel to the plane of the scale.

The scales of *Ornithoptera* are somewhat different from those just described, but may well be classified with them; *O. poseidon* is a typical example.¹ Its wings exhibit only moderate color change with angle varying from somewhat yellowish green to blue-green. At grazing incidence an orange-red sheen is visible in certain azimuths.

Structural Features. The scales themselves are nearly oval, highly convex, and over-lap on the wing very closely. They are uniform in thickness, and much less flexible and fragile than the scales previously studied. No coarse striation or mesh structure is present, but with high powers very fine and regular striations (about $1\ \mu$ between centers) are visible on the upper surface of the scale.

By transmitted light the structure appears to be simple, a plate of slightly turbid chitin with a finely striated upper surface; by reflected light it is seen that the body of the scale is not optically homogeneous but shows a fine stippling of reflection color. This is independent of the striations, and is visible from either surface of the scale. It is distinctly beneath the striated surface. Individual bright points of this stippled coloring appear to show something approaching specular reflection.

¹ Dr. Forbes points out that it is rather surprising that *Papilio philenor*, which is really one of the *Ornithoptera*, should have scales so different from the other members of this genus.

Fractured or distorted scales show little tendency to cleavage along the striations, and these cannot be isolated or flattened sidewise. There is little indication of a cleavage in the plane of the scale, but the edges of the fractures show some evidence of a lamellar structure.

Cross sections show that the striae are closely packed, between 1 and 2 μ high, and might equally well be thought of as a system of fine parallel grooves in the upper surface of the scale. The body of the scale appears rather more turbid than the upper or lower portions, but the differentiation between the cuticle and the interior is not very pronounced under the microscope. Oblique, broken, or distorted sections show distinct evidence of a laminated structure which apparently extends throughout the interior of the scale, parallel to the surface. This portion is not visible if the section is penetrated by a liquid, but on evaporation and entry of air, its opacity increases.

Optical Features. The most distinctive characteristic of the scales of *Ornithoptera* is the absence of true specular reflection. The scales show "high lights," but these are not sharply defined, and there is obviously a certain amount of diffuse reflection. Because of this, their lustre is hardly metallic, and their coloring less bright than that of the *Urania* scales. On the other hand, the color is visible over a wider angle. The reflection from either surface of the scale is essentially the same, for the striae are hardly visible except by transmitted light. On focusing up and down through the scale with an objective of very low "penetrating power" the reflecting surface cannot be definitely located; instead, reflection appears to take place from any level. This is borne out by study of the under side of the scale.

The reflection coloring of the scales is matte rather than metallic; yellowish green predominates, and the scales are remarkably uniform in hue. They are strongly colored by a non-granular yellow pigment, and this undoubtedly modifies both the reflection and the transmission colors. By transmitted light the scales are orange pink.

The orange-pink transmission color is what is seen at grazing incidence when the scales are on the wing. This may be studied under the binocular microscope and the various reflections and transmissions of the light by the overlapping scales may be clearly seen. The convexity of the scales is a considerable factor in the "reflection" of their transmission color, for light may be totally reflected at the lower surface of the scale, and travel a considerable distance in it before emerging. It is also noted that the orange sheen is greatest when light falls across the striations of the scales as they lie parallel on the wing. Here the yellow striae, which project above the portion of the scale where the green color originates, present an ideal finely divided transparent medium to scatter and to color the light which falls across them. Moreover, the curvature of the surface is greater crosswise. No orange sheen is observed on the *under* surface of scales stripped from the wing as a group. Their reflection color is green (instead of yellowish green), changing to violet at grazing incidence. If the scales on the wing are surrounded (but not penetrated) by a liquid their surface reflection is minimized, and the color from the interior shows up clearly at any angle, with none of the orange sheen.

The color of the scale varies with the angle of incidence, the reflected yellowish green changing toward blue and the transmitted orange-pink toward yellow. Polarization effects cannot be observed distinctly on account of the scattering of the reflected light.

Swelling reagents cause less alteration in the color than in the case of the *Uranidae*. The green becomes more yellowish, and the transmission color becomes more pink. These changes are reversed on exposure to the air.

Pressure brings about a very distinct change in the reflection color, from green through blue to reddish purple, before it is finally destroyed. The transmission color loses its pink and finally only the yellow of the pigment remains. Removal of the pressure with exposure to a moist atmosphere is sufficient to restore the original hue. Pressure on swelled scales first restores their original color and then alters it as indicated above.

Penetration by liquids is not so rapid as in *Urania* scales; the scale may lie completely immersed in liquid for some minutes before it is affected, though broken scales are more rapidly permeated. With a liquid of index of refraction near that of chitin (1.5 — 1.6) the iridescent color is perfectly destroyed and only the yellow pigment color remains. Removal of the liquid restores the original coloring. (Most liquids have a certain amount of swelling action, judging from the "lag" between the restoration of color and lustre, and the recovery of the original hue.)

The progress of penetration by liquids is similar to that in *Uranidae*, and is independent of the striae. The loss of color is gradual and more or less by stages, a given spot on the scale appearing less and less green until all its reflection color is lost. On evaporation of the liquid, irregular patches of faint color first appear, and, as these extend throughout the scale, successive additional patches of color appear, developing over the areas already colored; finally the original saturation of hue and intensity of lustre is completely restored.

Morpho and Similar Scales

In a number of respects the iridescent scales of the well known family of *Morphos* are different from those of the insects just described. A brilliant, highly metallic blue is the prevailing color, and this is present only on the upper surfaces of the wings. The variation in hue with change in angle of incidence is easily observed, reddish purple being the extreme color noted. The reflection colors are seen best looking from the base toward the tip of the wing ("with the grain" of the scales). This is only partly due to the inclination of the scales on the wing.

Structural Features. The scales of the *Morphos* are practically plane, and lie close to the wing, like shingles on a roof. *M. menelaus* has a double layer of iridescent scales. The outer ones are very thin, long, and narrow, shaped like the blade of a paddle, with longitudinal striae rather far apart (ca. 1.5-2 μ) and standing up like vanes on the upper lamella of the scale. Broken or crushed scales show these vanes flattened or torn loose from the scale proper, while scales folded crosswise permit their elevation to be seen; they are from 2 to 3 μ high. The vanes usually break cleanly, but may give evidence of a

longitudinal "cleavage" slanting very gradually from the upper edge to the base. There is no indication of a hollow interior in the scale.

Optical Features. On account of their great transparency the outer scales are best studied after being removed from the wing. On examining them by reflected light with a 4 mm. objective, it is evident that the vanes are the seat of the color, and that the laminae of the scale do not contribute to its iridescence. The reflection consequently is not specular from the surface of the scale as a whole, but is so from the upper edges of the vanes.

Torn or split scales, in which the vanes are loosened or removed from the lamina of the scale afford convincing proof of this; a single, isolated vane shows just as brilliant reflection and color as when in its normal position on the scale. However, with axial illumination and an objective of narrow aperture, no reflection is noted even though the plane of the scale is perpendicular to the illuminating beam. It is only when markedly oblique illumination is supplied that light is reflected up along the axis of the microscope. Evidently *the reflecting structure is not parallel to the plane of the scale*. This may be confirmed by tilting the scale until it reflects along the axis of the microscope with vertical illumination, or by rotating the stage in the plane of the scale after the illumination has been adjusted to such an obliquity as to be reflected along the axis of the microscope. In the latter case the vanes appear bright only once in a revolution; this behavior corresponds to the "oriented lustre" of etched metal specimens, and of laboradorite, cats-eye and similar minerals, all of which possess systematically arranged reflecting surfaces oblique to their own general surface.

The plane of reflection by the above tests is found to "dip" toward the root of the scale, making an angle of between 10° and 20° with its laminae and with the edges of the vanes. Since there is practically no reflection from vanes flattened in the plane of the scale, it appears that the tilting of the reflecting structure is only lengthwise of the scale, and that it passes through the vanes rather than following up one side, over the upper edge, and down the other side.

The "dip" of the reflecting plane in the vanes is the equivalent of tilting the scale on the wing, so that although the scales of the *Morphos* lie nearly flat, the reflection from the wing surface is that corresponding to markedly inclined scales. The intensity of the reflection is very marked, the narrow edge-views of the vanes appearing as highly luminous blue lines.

The iridescent color is obviously of structural origin and connected with the peculiar reflecting properties of the individual vanes, since it shows its full intensity on an isolated vane or on vanes which have been twisted laterally, and does not depend on their arrangement or proximity to other vanes on the scale. The color changes with angle from greenish blue for illumination normal to the reflecting plane to purplish red at grazing. If the color change is referred to this plane, it is consistent for all azimuths, but if referred to the plane of the scale the behavior is not so simply described.

As seen by reflected light, the edges of the vanes are not clear lines of blue, but each one is crossed, at intervals of $1-2\ \mu$ or more, by fine dark markings, which give them a somewhat "beaded" appearance.

By transmitted light the scales are seen to be unpigmented, and only faintly yellow along the color-producing vanes.¹

Polarization effects comparable to those shown by *Urania* and other similar insects are not to be observed accurately on account of the complexity of the surface of the scales, and the strong possibility of interference by polarization from its deeply ribbed structure.

Between crossed nicol prisms the scales are seen to be anisotropic with parallel extinction; this is purely a structural phenomenon, since it is destroyed by permeation of the scale with liquid of the proper refractive index. The anisotropy is localized in the vanes, a single isolated one showing it fully. When the vanes are flattened by pressure or distortion of the scale they are only faintly anisotropic. The extinction shown by the vanes seen flatwise is not sharp, on account of the weakness of their polarization color, but is apparently parallel or of small obliquity.

With one nicol the scales may show an apparent pleochroism, blue for vibrations parallel to their vanes, and greenish for transverse vibrations. This is related to the diffraction color described on page 327 (footnote 5). The blue is at a maximum for vibrations parallel to the diffracting structure; diffraction is at a minimum for vibrations perpendicular to this direction, and the blue, lessened in intensity and combined with the pale yellow transmission color, appears greenish.

The reflection colors of the scales are less variegated than are those of the insects studied previously, though tints of green and purple may be seen mingled with the blue; a single vane may show slight non-uniformity of hue in different parts.

Pressure may flatten the vanes sidewise, destroying their reflection, but if this does not occur the hue is seen to be altered through dark blue and violet to reddish purple. It may be restored by exposure to a moist atmosphere.

Swelling the scales with phenol vapor causes the hue to change to yellowish green (going to violet at grazing). The original coloring is restored on exposure to the air.

Penetration by liquids of index of refraction close to that of chitin ($1.5-1.6$) results in complete loss of color. The original color is perfectly restored on removal of the penetrating liquid. Liquids of refractive index markedly lower than that of chitin cut down the reflection color somewhat, and alter its hue to yellowish green, which is due partly to swelling, and perhaps also to the replacement of air in the scale by a medium of higher refractive index. Wetting of the under lamina of the scale by the liquid does not alter the color, this occurs only when the liquid penetrates between the vanes and wets them thoroughly. On evaporation of the permeating fluid the color only reappears

¹ Onslow was disturbed by the fact that the scales may appear blue both by reflected and by transmitted light, but the latter is true only with objectives and illumination of the proper relative aperture, and is due to the causes indicated above (page 327, footnote 5).

after the vanes have been exposed, there is frequently an appreciable time interval after their exposure before the color develops in each vane separately.

The under scales of the upper surface of the wings of *M. menelaus* are superficially different from the transparent outer scales, but are similar in all important features.

Structural Features. The scales are flat and broad with blunt, uneven ends, and are very closely striated longitudinally. These striae are really fine vanes, as in the outer scales, so closely spaced as to be, practically in contact, with no space visible between them. They are less than $1\ \mu$ between centers, though not perfectly even or parallel, and project about $2\text{--}3\ \mu$ above the upper lamella. They may extend slightly beyond the tip of the scale. Fractured scales show that the vanes and upper lamina constitute the greater portion of the scale, and that the lower lamina is a simple thin membrane. Fractures tend to follow the vanes, giving the scales a well defined longitudinal cleavage. On account of their close packing, the fracture of the individual vanes is not readily studied, nor are they easily flattened sidewise.

Optical Features. The reflections from the scale originate in the individual vanes, and are seen only when these are in their normal position, perpendicular to the plane of the scale. A single isolated vane exhibits the full color and lustre. The reflecting plane is not parallel to the edge of the vane and in the plane of the scale, but is inclined to these, dipping toward the root of the scale at an angle of between 10° and 20° . With respect to this plane, the reflection is specular enough so that it is observed through a narrow angle only for any given angle of incidence.

In contrast to the outer scales, the under ones are pigmented fairly heavily, with a dull brown pigment, which is dilute in the lower lamina and is mostly in fine granules along the lines of the vanes. Since the scales are dark from the under side, it is evident that the pigment is mainly beneath the vane.

The under scales show color changes with varying angles of incidence precisely similar to those exhibited by the outer scales. Their polarization effects by reflected light are not well defined. Between crossed nicols they show anisotropy of structural origin, with parallel extinction, flattened vanes seem to show slightly oblique extinction.

On account of the close proximity of the vanes on the scale, pressure can be very effectively employed without flattening them sidewise, and the sequence of color changes from the normal light greenish blue to purplish red is easily observable. Their behavior on swelling is the same as that of the outer scales.

Penetration by liquids reveals the presence of a spongy interior, to which the thick, pigmented upper lamina with vanes is attached. Pressure on the empty scale forces air out of the interior and bubbles may be seen in the surrounding liquid, or if the scale is filled but not surrounded by liquid, this may be squeezed out as from a sponge. The scale possesses a considerable amount of elasticity. On drying out, the vanes are cleared of liquid first, and their color is restored. At the same time, or immediately after, the spongy interior empties, and the opacity of the scale increases further. The restoration

of the color on drying is along the vanes, as is its destruction on penetration. The condition of the interior of the scale or of the lower lamina does not govern the appearance of the color. The lower lamina has a slightly wavy surface, and is iridescent from either above or below. It is similar to the iridescent lower laminae possessed by nearly all butterfly scales, and plays no part in the color of the scales on the insect.

The scales of *Morpho sulkowskyi* ("Pearl Morpho") have practically the same optical properties and structural features as those of *M. menelaus*. The pigmented scales are a deep brownish orange by transmitted light but this is not all due to pigment, for penetration by a liquid of $n = 1.55$ destroys all transmission color but a weak grayish brown. Pressure also destroys much of the color. This dark orange transmission color is related to the blue reflection color, for it develops simultaneously with it as the permeated scale dries out.

The scales are distinctly pleochroic, from dark orange for vibrations crosswise of the vanes to lighter orange for vibrations parallel to them; this pleochroism is lost when the scale is penetrated by a liquid.

A number of other butterflies have scales which are similar in their optical properties to those of the *Morphos*. *Apatura (chlorippe) seraphina* is a widely studied example, which shows the vaned scales and inclined reflection typical of the insects just described. In the violet scales near the outer edge of the wing, the plane of reflection is distinctly more tilted than in the *Morphos*, and makes an angle of about 30° with the plane of the scale. The vanes of the scale, flattened sidewise, show oblique extinction, at an angle between 20 and 30° . The scales in the brilliant greenish blue band across the center of the wing have less inclined reflection, and their vanes do not show markedly oblique extinction when seen flatwise. *Apatura ilia* is similar in optical behavior to *A. seraphina*, but its colors are not as brilliant, possibly because of greater pigmentation; they range from greenish blue, to reddish purple at grazing incidence. The tilting of the reflecting plane, and the localization of the iridescence in the vanes are unmistakable.

Ancyluris meliboeus is another insect having scales with iridescent and inclined reflection. It exhibits a very brilliant lustre, and colors similar to that of the *Morphos*, showing rather more variation in hue with increasing incidence, with pressure or with swelling. The reflecting plane makes an angle of 10° - 20° with the plane of the scale.

Callicore eluina has scales showing practically identical properties with those of *Ancyluris meliboeus* as regards their hue and its changes with pressure, swelling or varying angle of incidence.

The *Morphos* and the specimens described after them constitute a second group with essentially similar optical and structural properties throughout. They are characterised by their vaned scales, the iridescence of which is localized in the individual vanes. The fact that their reflections do not originate in the plane of the scale but in a plane making an appreciable angle with it, is another distinctive feature. The lower lamina, though iridescent, is a negligible factor in the color of the insect.

The structural origin of the color and its changes with varying incidence, with pressure, and with swelling, are analogous to these properties as observed in the scales of *Urania* and other insects of similar nature.

Beetle Scales

The scale-bearing beetles have many points in common with the above moths and butterflies as regards their iridescence. *Entimus imperialis* ("Brazilian Diamond Beetle") is the best known of these, and is typical of them as a class.

Structural Features. The scales which line the pits in its integument are flat, paddle shaped or more elongated, with no ribbed or meshed structure. Their upper and lower surfaces appear structurally identical.

Fractured scales, or those torn by a fine needle show indications of a lamellar structure, the broken boundary is like the torn edge of several sheets of paper. Sections of the scales furnish little additional information. The "cuticle" of the scale is about $1\ \mu$ thick, and the interior of the scale is $4-6\ \mu$ in thickness. Both cuticle and scale contents appear practically void of structural details; the interior portion is not perfectly clear and glassy, but no direct evidence of a lamellar structure is apparent. In plan the scales show a very fine and rather indistinct pattern of lines, substantially equidistant, and more or less curved, resembling a portion of a finger print or lamellar "pearlite" in steel. The slightly curving lines may extend from edge to edge of the scale, and may run across it at any angle. On some scales there are sharply defined areas (coincident with the patches of various colors) in which the lines run in different directions.

Optical Features. Blue-green is the most common reflection color of the scales of *Entimus imperialis*, but some may show yellow-green or orange. These colors are very brilliant and lustrous, as seen from either surface of the scale; dark field illumination shows a certain amount of scattering of light by the interior of the scale. This results in a somewhat "opalescent" appearance, and the reflections instead of being strictly specular, may be spread through an appreciable angle. However, this scattering is slight, and the general effect is that of highly metallic lustre on the individual scales.

The plane of reflection is not always parallel to the principal plane of the scale, and may be inclined appreciably from it. This may be observed readily with axial illumination and axial observation as obtained by an objective with iris diaphragm and a vertical illuminator. The scale may be shown to be flat against the slide on which it rests, by the observation of the colors of Newton's rings between it and the glass. The tilting of the slide necessary in order that the scale shall reflect axial light back along the axis of the microscope may be measured; angles of 10° to 15° are not uncommon. This tilting of the reflecting plane is also evidenced by the swaying of the image with reflected light on focussing up and down. It may also be observed, with strictly vertical illumination, at the back aperture of the objective; the reflection color is seen to be markedly off center. Movement of the reflector in a mirror-type vertical illuminator, to furnish oblique reflected illumination also

demonstrates the inclination of the reflecting plane, particularly if the stage is rotated, when "oriented lustre" may be seen very strikingly.

When the scale is inclined to the axis of the microscope so that its reflecting plane is perpendicular to the axis, rotation of the stage reveals no "oriented lustre". With the scale more inclined to the axis, rotation *in its reflecting plane* causes no change in lustre or hue.

The anomalous reflecting properties described above are related to the structure and color of the scale; the different colored areas, in which the striations run in different directions, show inclined reflections which are sharply defined by their boundaries. The tilting is always *crosswise* of the striae, and is less where they are farther apart. With a scale half yellow and half green by reflected light, the yellow image sways in one direction while the green sways in another, on passing out of sharp focus. At the back aperture of the objective the green is seen to be at one side of the lens and the yellow at the other. In general the correlation between reflection, striation and reflection color is very distinct on these varicolored scales. When the color is uniform throughout, or only shows gradual variation in hue, the behavior is not so spectacular, but the inclined reflecting plane may be recognized in any of the scales where the striae are visible, and in most instances the angle of inclination is sufficient to prevent its being overlooked.

The reflection colors are uniform in hue in uninjured scales; a scale may be one color throughout or may be divided into areas of different colors. These areas are sharply defined, and constitute a "mosaic" of colors on the scales; ordinarily 2 to 5 patches of color are found on a single scale. The boundaries of these colored areas show no gradation of color, and are usually almost straight lines. Their outlines coincide with those of areas where the striations run in different directions, and where the reflection plane is tilted differently. Gradual variations in color are less common, but may frequently be noted in scales which have been altered by pressure. Pigment is wholly absent from the scales.

The reflection and transmission colors bear a complementary relationship to each other, and this is consistently true throughout the local variations in hue, so that the mosaic pattern is sharply defined either by transmitted or by reflected light. The reflection colors, brass-yellow, green, and blue, have respectively corresponding transmission colors of purplish blue, purplish red, and yellow. The transmission colors are very highly saturated. It sometimes happens that illumination with reflected light may reveal flashes of red, but this is really the transmission color seen by virtue of light reflected up through the scale from its under surface or from some surface beneath the scale itself.

The color of the scales changes with the angle of incidence to a marked degree. This may be observed either by tilting the scale, or by oblique illumination, either transmitted or reflected. With an objective of N. A. 0.95 narrowing the aperture by means of a diaphragm changes the hue by cutting off the oblique rays and permitting only the axial portion of the cone to pass; this is particularly noticeable with transmitted light, and serves as a means of observing the pure color for one angle of incidence only. With axial trans-

mitted illumination the scale may be tilted and then revolved in its own plane; the transmission color does not change appreciably.

With increasing incidence the reflection colors pass from brass-yellow through green and blue to purple, and the corresponding transmission colors through purplish blue and red to orange or yellow.

The scales seen flatwise are isotropic between crossed nicols. Their reflection, analyzed by a nicol prism, shows the same behavior as *Urania* scales: at all angles of incidence, the same color for vibrations perpendicular to the plane of incidence as for unpolarized light; for angles greater than about 60° , complementary color for vibrations in the plane of incidence. Elliptical polarization is identified by means of a " $\frac{1}{4}$ undulation" mica plate. The above tests are not easy to carry out, on account of the inclined reflecting plane, but the behavior is unmistakable when observed.

Since the scales have no prominent striations it is possible to test for any diffracting properties by illumination with a narrow cone of transmitted light; no diffraction spectra are visible in the back aperture of the objective, so no systematic ultramicroscopic structure of lines or dots is indicated. This is confirmed by unilateral (dark field) illumination. The colors are undiminished in diffuse light.

Pressure affects the coloring very strikingly. The patches of color tend to be rendered uniform in hue, and then the transmission color goes through purple, red and orange to yellow, and finally to colorless, the reflection color changes from brass-yellow through green, blue and reddish purple, to dark red and orange. The color is restored on standing a few minutes, or more rapidly by breathing on the scale.

Swelling also alters the color, in a sequence of hues the reverse of that passed through with increasing pressure. Exposure to the air restores the original coloring.

Penetration by liquids is significant, for it reveals the entire absence of pigment, and the structural nature of the coloring. With a liquid of $n = 1.55$ the reflection and transmission colors are destroyed completely. If the index of refraction is much greater or less than this value, the color is diminished in intensity but not wholly lost. The hue is altered somewhat, either because of swelling or because of the replacement of air by a more refractive medium. The original coloring is perfectly restored on removal of the liquid.

Liquids do not readily penetrate uninjured scales, but if they are torn or if their root affords an opening, the liquid enters and spreads rapidly throughout the interior. The process of penetration may be followed more easily if viscous liquids are used, and it is seen that the advancing front of the liquid is not a simple meniscus in the interior of the scale, but that it progresses in layers at different levels. The advance of these is practically even, but their fluctuations add to the appearance of a laminated interior. The loss of color coincides with the advance of the liquid in all levels; if only a part of these are permeated, the color is lessened but not destroyed. Where a boundary between two patches of color is encountered the penetration is momentarily interrupted, as if there were a break in the continuity of the voids through

which the liquid flows. The cuticle remains unaffected in the above process, and is evidently nothing more than a clear structureless membrane enclosing the interior of the scale, where the color is localized.

One of the most beautiful of the scale-bearing beetles, *Hadiomeas gemmifer*, has scales which are optically and structurally closely analogous to those of *Entimus imperialis*. They are mushroom shaped, with the root near the center of the lower surface, and are nearly circular in outline, but, apart from these differences, they show the same details of structure observed in *Entimus imperialis*. The patchy, inclined reflection, the hatching of fine lines in each of the differently colored reflecting areas, and the lamellar cleavage of the broken scales are even better defined. The increase in spacing of the surface striae with decrease in tilt of the reflection plane is very evident, and resembles the appearance of "pearlite" surfaced where its lamellae are inclined.

The whole set of optical properties, color distribution and alteration, and the behavior on penetration by liquids are the same as those of the preceding specimen.

Another scale-bearing beetle, representative of a widely studied species, is *Cyphus varnhageni* Germ. The structural and optical properties of its scales correspond closely to those of the two preceding specimens. The scales are oval, attached to the integument at one end, and their color is even more "patchy"; a mosaic of 10 or 15 colored areas may be seen on a single scale. The striae in these colored areas are well defined, but far from regular in many instances, and may have almost a *moiré* appearance. Correspondingly, the reflection is less perfectly specular.

Because the scales are divided into so many colors, and have such small reflecting areas, they do not appear as metallic to the naked eye as those of the specimens just described.

Eupholus azureus is even less metallic, and appears to have almost an "enamel" lustre; under the microscope small, closely adherent, deep blue scales are visible. On the under parts of the insect these shade into lighter greenish blue. Microscopically they are very similar to the scales of *Cyphus*, with numerous patches of color (violet to greenish-blue) on a single scale. The reflections are inclined and the striae are relatively irregular. The small size of the scales, and the number of reflecting patches on each gives a matte lustre to the specimen.

Another beetle, *Hoplia cerulea*, appears to constitute an exception to the general type of optical and structural properties shown by the scale-bearing beetles, in that there is no inclined reflection or mosaic distribution of coloring in the scales. These have slightly embossed or "pebbled" surfaces, which reflect specularly, and spread the light over an appreciable angle, so that to the naked eye they are only moderately metallic. The laminated fractures, behavior on penetration with liquids, and color changes with angle, pressure, or permeation are the same as shown by the scales of the other beetles.

Iridescence of Scales compared with that of Thin Films

The properties of the scales presented in the preceding pages need hardly be compared item by item with those of gratings or selectively reflecting substances to eliminate these from further consideration; their whole behavior is definitely at variance with either of these explanations. On the other hand, in spite of the efforts of the writer to avoid introducing the terminology of thin-film colors, the reader can scarcely have missed the rather striking resemblance between the behavior of the scales and that of thin color-producing films. That this resemblance is more than superficial is substantiated by detailed comparison of their optical properties.

1—The reflections are specular; a definite angle of incidence has a correspondingly definite angle of reflection. Microscopic "high-lights" on scales which are not perfectly plane demonstrate this plainly. Diffuse illumination does not cause the color to disappear.

2—The intensity of the reflection is high. This is true for a single thin film, as may be shown by means of a "model" prepared by picking up a colored film of varnish which has spread and hardened on the surface of water. Such films are highly metallic, with brilliant reflections. Multiple films, such as those of old Roman glass or iridescent KClO_3 crystals are even more perfect reflectors.¹

3—The colors of the scales are readily recognized by comparison with artificial thin films, as corresponding to those of Newton's series, in the second or lower third orders.

4—The relationship to Newton's series is confirmed by the change in hue which takes place with increasing angle of incidence. In every instance, this is toward a color *lower in order*, and duplicates that of an artificial thin film held parallel to the reflecting plane of the scale.² The color change is marked, even with a rather small change of angle, and, to one who is familiar with the appearance of thin-film colors, is very characteristic.

5—The color produced on swelling the scale is predictable in all cases as that corresponding to an *increase in order* (thicker film). The swelled scales behave in all respects the same as the untreated ones.

6—The changes of color produced by compression of the scale are predictable in all cases as corresponding to a *decrease in order* (thinner film). This agreement is so perfect that the zones of altered color surrounding a compressed spot on a single scale are precisely similar to a portion of Newton's series. Moreover, the actual change in color may be witnessed under the microscope, and the gradual restoration of the color may also be followed. The destruction of color with extreme pressures corresponds to bringing the laminae into optical contact.

¹ These model thin films, single and multiple, are invaluable in the study of the optical properties of such systems. They are also useful in convincing people who, on the basis of their experience with soap-bubbles, doubt that such films are capable of exhibiting color and lustre equal to that of insects.

² This "decrease in order" of the color usually means a change toward violet (the color lowest in the second order) and some writers have tried to use this as evidence for selective reflection, but in a number of specimens the analogy breaks down completely. The change in hue is much greater than with any surface color known to the writer.

7—The distribution of colors on the scale or on the wing corresponds to slight variations of position in the series, (variation in thickness of film). Unless the coloring is in sharply defined patches the colors adjacent on the scale are those adjacent in the Newton's scale. The variation in hue may be very pronounced in the space of a few microns, in a manner more intricate than any possible pigment distribution.

8—The reflection and transmission colors are truly complementary in hue, if pigment is absent or neutral in color. This is true for all variations of angle, pressure, swelling, and distribution on the scale, so that the above paragraphs (3, 4, 5, 6, 7) describe both transmission and reflection colors.

9—In general the transmission colors are less saturated than the reflection colors, though for multiple films this difference is not so pronounced. (cf. the description of the flakes of decomposed glass, on page 324).

10—The polarization properties, where observable, are in full agreement with those of the reflections from thin color-producing films.¹

11—The disappearance of iridescent color and metallic lustre when the scale is permeated by a liquid of its own index of refraction corresponds to that of thin films under similar conditions. The fact that liquids markedly higher or lower in refractive index do not cause complete loss of color is also consistent, particularly since the transmission color is diminished much more than is the reflection color.

12—The absence of any but neutral brown pigments, and of any diffraction phenomena likely to cause color is negative evidence of considerable significance.

The criteria enumerated above indicate the very close similarity between iridescent scales and thin film colors as regards their optical properties. Quantitative optical studies by Rayleigh and by Merritt also emphasize this resemblance. A single thin film is hardly an adequate postulate,² on account of the saturation of the transmission color, but multiple films are capable of exhibiting all the phenomena of the scale colors, and several writers³ have come to the conclusion that they are the cause of the iridescent coloring.

In the opinion of the writer such a conclusion is justified on the basis of optical tests alone, but certain structural evidence is available which may have more weight with biologists, particularly since it throws light on the arrangement of the color-producing structure, and is wholly consistent with the optical phenomena exhibited. The essential structural features are as follows:

1—Lamellae, more or less parallel to the plane of the scale, are visible at fractured edges. Distorted sections may show lamellae separated.

¹ Preston: "Theory of Light," 362 (1901).

² v. Lengerken (Biol der Tiere Deutschland, (Schulze) Lief. 12, Teil 40, p. 55) and Biedermann (*loc. cit.*) thought that "a thin layer of air between the two lamellae of the scale, functioning as a thin film" caused the color in most cases. They do not appear to recognize the possibility of multiple films or the inconsistency between the thickness of the interlamellar space and the colors produced.

³ Stüffert is the only one who bases his opinion on more than a few of the above points of likeness.

2—Penetration of viscous liquid through the color-producing structure is not instantaneous, but tends to proceed in layers, as if it were filling in the spaces between the lamellae.

3—Lamellae inclined to the plane of the scale are indicated by their successively projecting edges, which give the "beading" on the vanes of *Morpho* scales and the "finger-print" or "pearlite" pattern on the color patches of the beetle scales.

4—The dimensions of the color-producing structure are consistent with the type postulated, the lamellae of which would be only about 0.3–0.5 μ thick at most. There is space for a number of such films in any of the specimens examined.

The practical impossibility of any direct observation of the lamellar structure in sections perpendicular to its planes is to be expected from its dimensions, but it must be emphasized that the other evidence more than compensates for this deficiency.

As to whether the color-producing films are air between chitin, or chitin in air, or both, one cannot be certain, but since swelling agents (phenol vapor, etc.) alter the color in the direction corresponding to a thickening of the films, they may well be composed of chitin. If they were air, swelling the surrounding chitin should tend to thin them, unless some separating material swelled with the films and "opened" the air spaces.¹

Assuming chitin films, the space between them need be very thin; an air film of thickness much less than that required to produce color would still serve to keep the chitin lamellae from being in optical contact, so that the distance between centers of the various planes might be little more than their thickness.²

The formation of such a systematic structure, remarkable as it is, puts no more strain on one's imagination than some of the other minutely intricate structures in insects; the lamellae are perhaps formed as a result of rhythmic precipitation in the scale, analogous to that involved in the synthesis of mother-of-pearl.³

¹ Suffer puts a good deal of stress on the change in hue observed when the laminar structure is permeated by a liquid; he considers this as due to air films being replaced by films of liquid; of greater *effective* thickness because of higher refractive index. However, the scales are very susceptible to swelling by most liquids, and this would bring about the same sort of color change. This is evidenced by the fact that although the liquid may have been completely evaporated from the scale so that its full lustre and saturation of color is restored, the hue is frequently different from the original one, which is only regained after a moment's further exposure to the air.

² In all probability there is a small amount of structureless tissue irregularly distributed between the lamellae, since liquids do not spread perfectly evenly between them. This would help to maintain the films separate, and to restore them if they were pressed into perfect optical contact.

The air is so thin that india ink (carbon particles less than 0.2 μ) is filtered, and only the aqueous vehicle penetrates between the lamellae.

³ Ganguly: J. Chem. Soc., 1926, 1381. Evaporation of gelatin and $\text{Ca}(\text{HCO}_3)_2$ solution yields an iridescent, laminated structure of CaCO_3 .

Applications of the Thin-Film Theory to Type Specimens

The scales of the insects described above are alike as far as their important structural and optical properties are concerned, but there are certain points which need to be discussed more in detail because people have misinterpreted them in the past.

The *Uranidae* and other insects having scales of this type make no special demands on the theory; the multiple films may be in either lamina of the scale. Their plane is that of the scale, and in all respects their optical behavior is consistent with that of a system of multiple thin films, (say five to fifteen); the superposition of a vaned or meshed structure on the outer surface of the upper lamina modifies the visibility of the film colors, but does not prevent the recognition of their typical properties.

FIG. 1

Scale of *Urania* type (schematic).

- A—thin vanes or ridges comprising longitudinal striations
- B—multiple films, the seat of the color.
- C—lower lamella

Details of upper and lower surfaces may vary.

The pearly iridescent scales of *Argynnis* are of the same type as those of *Urania*, with no pigment, and less uniform films. The hues are recognizable as adjacent in the second order of Newton's series. The low intensity of the coloring may be due to only one or two films being present, or to the films not being alike in thickness, so that their colors tend to neutralize each other. The former explanation appears more probable from the appearance of the coloring.

The color-producing structure in the scales of *Ornithoptera poseidon* is essentially the same as that in *Urania*, but is enclosed within a dense "cuticle," and is less continuous in character, as indicated by the irregular loss and restoration of color with penetrating liquids. Also the reflecting surfaces are less perfectly plane, or are interrupted by intermediate tissue; the scattering of light and the finely stippled appearance of the scales by reflected light are

evidences of this. It may well be that the various lamellae are more or less "embossed" or that they are rather firmly supported by some sort of interpenetrating structure, or both these conditions may exist. This would account for the exceptionally great mechanical strength and rigidity of the scale, its lack of sensitiveness to pressure, and the moderate change with swelling agents.

In the case of the *Morphos* and other scales with inclined reflection localized in the vanes on their upper surface, the situation is rather more complex. As Süffert has demonstrated so convincingly, the lamellae must be inclined in

FIG. 2

Scale of *Morpho* type (schematic)

A—longitudinal vanes, consisting of inclined multiple thin films, the seat of the color.

B—basal layer.

Proximity of vanes and complexity of basal layer may vary.

the vanes and dip toward the root of the scale. The minuteness of the reflecting lamellae prevents a detailed study of their structure, but the oblique fracture which the vanes sometime show and the oblique extinction exhibited by them when flattened sidewise afford some confirmation of the optical tests. The closely spaced cross-markings or "beading" on the vanes of some of the scales are probably the edges of the successive lamellae, and one might even go so far as to estimate their thickness from the spacing.¹ The air space between the vanes is of no importance in the production of color, since isolated vanes act quite as well as those in systematic arrangement on the scale.²

Michelson's observations of anomalous phase differences in the light reflected by the scales of *Morpho alga* are to be explained by the fact that he did not realize that the reflecting plane is inclined to the plane of the scale.

¹ Tilting, t , 10° – 20° . Spacing of edges, s , 1 – 2μ ; Spacing of laminae, $s \sin t$, 0.2 – 0.6μ .

² Onslow concluded that the vanes and the air layers between them acted as multiple films on edge. He apparently did not recognize that a single vane was capable of producing full color, or that the color may be seen with illumination strictly edgewise of the vanes. The vanes, seen flatwise, produce no color, though this position should give a maximum brilliancy according to Onslow's hypothesis.

He ignored completely the loss of color on penetration, yet concludes in favor of "surface color", not only for *Morpho* and *Papilio* but for all iridescent butterfly scales.

Entimus imperialis is typical of the scale-bearing beetles, which reflect light from a plane not parallel with that of the scale, and which frequently show several sharply defined, differently colored reflecting areas on a single scale. Here the lamellar structure fills the interior of the scale, and is enclosed by the cuticle. The lamellae are tilted in different directions in the different "patches" of color, and the "finger-print" or "pearlite" pattern in these is

FIG. 3

Scale of *Entimus* type (schematic)
 A—multiple thin films, the seat of the color.
 B—"cuticle" enclosing lamellar structure.

from the edges of the successive thin films. The lines of this pattern closest together where the films are inclined most, and where they are farther apart the tilt of the reflecting surface is measurably less¹ (just as the grain of wood is varied by cutting more or less tangentially).

Biedermann and Mallock, who studied *Entimus* and *Cyphus* scales, considered their color to be due to thin films; Michelson admitted that the color could not be ascribed to selective reflection, on account of its destruction on penetration with liquids, but "the colours exhibited by these scales are so vivid and varied, and the changes so rapid with varying incidence that it was at once evident that the effect must be due to diffraction from regular striations" so he proceeded to calculate their interval and to postulate a "saw-tooth" grating structure. He concluded that "the colour in this case is due to fine striations on the interior surface of the scale." Onslow doubted this on the basis of the brilliant transmission colors, the lack of sufficient regularity of the "striations," and the unimpaired coloring in diffuse light. He found

¹ Calculations of the spacing of the laminae (cf footnote 1, page 352) indicate a distance of probably less than 0.3μ between centers, which is in very fair agreement with the thickness of film corresponding to the colors exhibited by the scales.

evidence of inclined multiple films in some of the sections he studied, but in spite of all this he is apparently undecided between thin films and some sort of a "laminary grating" as the cause of the color. The second and third of Onslow's objections just cited apply quite as well to this postulate as to Michelson's "saw-tooth" grating.

Conclusion

The positive and negative evidence presented in the foregoing pages fits together well enough to justify still further the opinion which so many workers have had in the past—that the colors of iridescent scales are those of thin films. Any other assumption will not fit the facts, while this one fits them in a most consistent fashion. Because the details of the color production have not been discussed very definitely by most writers, and because only a relatively small part of the evidence was mustered by any one of them, the writer was particularly pleased to read Süffert's paper on butterfly scales, which reached him when the present work was being written up. The criteria utilized and the conclusions drawn are very closely concordant. The extended treatment of the optics of thin films, single and multiple, and the excellent color plates are especially to be commended to the attention of the reader, as supplementing the present article. The entire work constitutes a most convincing corroboration of the thin-film hypothesis.

Iridescent scales about which there is any question will probably fall rather definitely into one of the three classes described above, and the application of the various tests and lines of reasoning outlined should enable those interested to deal with such specimens.

The conclusions of this paper are as follows:

1—Iridescent wing membranes owe their color to multiple thin films separated by material of slightly different refractive index.

2—Iridescent scales are of three main types, each of which owes its color to multiple thin films separated by air.

3—In scales of the *Urania* type the color-producing lamellae are parallel to the plane of the scale, and may be overlaid by a ribbed or meshed structure.

4—In scales of the *Morpho* type the color-producing lamellae are in the vanes on the upper surface of the scale, and are inclined toward the root of the scale.

5—In scales of the *Entimus* type the lamellae are enclosed by a cuticle, and are tilted in different directions in sharply defined areas.

6—The fine striations common on insect scales are not related to the iridescence visible under ordinary conditions.

7—Selective reflection ("surface color") is not exhibited by iridescent insect scales.

AQUEOUS SOLUTIONS OF SODIUM SILICATES. V. OSMOTIC ACTIVITY, LOWERING OF VAPOUR-PRESSURES AND FREEZING-POINTS

BY R. W. HARMAN

Introduction

In the elucidation of the problem of the behaviour of solutions of silicates, the osmotic activity i. e. the nature of the ions and their concentrations, plays a very important part. The determination and discussion of the concentration and activity of sodium ions and of hydroxyl ions of aqueous solutions of sodium silicates of varying ratios and concentrations have already been communicated.¹ Heretofore, the silica in solution has always been thought to be colloidal, due, no doubt, to preconceived ideas arising from the colloidal nature of silicic acid, using the term silicic acid in a wide sense to cover all those forms of hydrated silica or hypothetical silicic acids, met with in the literature. From conductivity measurements² and from transport number experiments³ evidence has been brought forward of the existence of silicate ions, and further work on diffusion through semi-permeable membranes to be communicated shortly leaves no doubt as to their existence.

The determination of the total concentration of the ions is perhaps the most important part of this investigation into the nature of aqueous solutions of sodium silicates. Having obtained a knowledge of the total crystalloidal content of these solutions, together with the hydroxyl and the sodium ion concentrations, the question of the relative amounts of colloidal and crystalloidal silica, with the possibility of ion adsorption, or of micelle formation, may be definitely discussed.

Of the many methods by which the osmotic activity of a solution may be measured, the lowering of the freezing point is, omitting exceptional cases, the best. The lowering of the vapour pressure is also capable of accurate measurement and has the advantage that it may be carried out at any temperature, thus obviating the necessity of correcting the osmotic pressure for temperature. Since a method of measuring the vapour pressure had recently been worked out in this laboratory and its application had met with success in an investigation on the activity of HCl solutions, it was decided to try this same method with silicate solutions; but the results as explained later, have not been altogether satisfactory. The freezing point method was then employed and the conclusions deduced herein are mainly from the results so obtained.

VAPOR PRESSURES

Experimental

The method was essentially the same as that used by Dobson and Masson¹ for measuring the vapour pressure of HCl solutions. It consists in saturating a measured current of gas, (nitrogen) with water vapour, by bubbling the nitrogen through the solution, and then absorbing and weighing this vapour. The vapour pressure follows from the gas laws when we know the volume occupied by the gas in the saturator.

The apparatus, made of hard glass, was a double apparatus, the first part consisting of saturators containing pure water followed by an absorber of H_2SO_4 , the other part, of saturators containing the silicate solution followed by an absorber.

The great advantage of this type of double apparatus is that it may be operated in two ways:—

(1) to measure the actual vapour pressure of the water and of the solution, called the absolute method, A.

(2) to measure the vapour pressure of the silicate solution relatively to that of the water, relative method, R.

In the first way, the volume and pressure of nitrogen saturated with water vapour, and the weight of water vapour so required to saturate it, must be measured, whence can be calculated both the vapour pressure of the solution and of the pure water, the latter thus serving as a check on the accuracy of the experiment. Operating in this way, the passage of about 10-12 litres of nitrogen meant an increase in the absorbers of from 0.2-0.3 gram. However, the greater the amount of water vapour absorbed and weighed the greater the accuracy of the experiment. This was better achieved in the second method of operation, where the nitrogen was allowed to bubble through for about 24 hours, whereby the amount of water vapour absorbed was from 1 to 2 gm. In this method of operation the volume of nitrogen was not measured, so only the vapour pressure of the solution relatively to that of the water could be calculated.

The experiments were carried out at 25°C, the apparatus being immersed in a water thermostat electrically heated and regulated to 25° C \pm 0.01.

The solutions used, their composition, concentration and preparation, the precautions taken, etc., were the same as those already quoted in the previous publications on this subject by the author.

Accuracy of Results

(1) *The absolute method, A.* The fact that the vapour pressure of water at 25° C can be calculated provides a most useful check and indication that the apparatus is working satisfactorily. One or two runs with each silicate solution experimented upon were usually made, but the values of the vapour pressure of water or of the silicate solution generally differed by as much as

¹ J. Chem. Soc., 125, 668 (1924).

error is not surprising when we consider that the accuracy depends upon.—

(1) The amount of water vapour absorbed. This was about 0.2 gm., the total weight of the absorber and the H_2SO_4 being about 50 gm.

(2) The measurement of the excess pressure in the saturator. This fluctuated slightly over a run, but with a constant-level device attached to the aspirator the pressure could be measured to within 0.1 mm.

(3) The measurement of the volume of nitrogen collected. This volume was accurate to within 0.01%. By using great care and making several runs with the same solution it was possible to obtain the vapour pressure to within

	R	—	23.64	0.06			

0.01 mm. With the more concentrated solutions of ratio 1 : 1, where the lowering is in the neighbourhood of 1 mm., this 1% error is allowable, but with dilute solutions, e. g. one containing 0.2N crystalloidal matter, where the lowering is only 0.04 mm., the error in the vapour pressure lowering is 25%.

(2) *The relative method, R.* By allowing the nitrogen to pass through from 24 to 48 hours the weights of water vapour absorbed were increased to % gm. and the error due to their measurement practically eliminated. The error introduced by the measurement of the nitrogen has entirely disappeared, the calculation now being independent of the volume of nitrogen. Therefore the accuracy depends almost entirely upon the precision with which the excess pressure in the saturators can be measured, and this as stated previously could be determined to within 0.1 mm. of mercury. This method gave much more concordant readings, the accuracy being within 0.005 mm% of mercury, but even this means an error of 10% in the lowering of the vapour pressure of a dilute solution containing 0.2N crystalloidal matter. Hence the reason for making freezing point measurements as well.

Results

In Table I are given the results of vapor pressure measurements for ratios $\text{Na}_2\text{O}:\text{SiO}_2$, 1:1 and 1:2. Under the heading method is given the manner (absolute, A, or relative, R) in which the vapour pressure was found. Column 7 contains the calculated value of the lowering of the vapour pressure for the cited normality for an ideal non-associating, non-dissociating compound and column 8 the ratio of the experimentally found lowering to that of the calculated lowering, in other words, the van't Hoff factor "*i*".

These results will be discussed and compared with the freezing point results given below. However, the older method of calculating the molecular weight or degree of ionisation, involving the assumptions and conceptions upon which the van't Hoff factor "*i*" is based is probably not so accurate or in as close accordance with experimental facts as some of the more recent theories. Therefore an attempt will be made to interpret these results from the point of view of the activity theory.

Calculation of Activity Coefficients for Ratios 1:1 and 1:2 from Vapour Pressure of Solvent.

The method of calculating the activity coefficient of a solute for concentrated solutions from the vapour pressure of the solvent, given in Lewis and Randall's "Thermodynamics", has been strictly followed and the results are given in Table II, where the notation employed by Lewis and Randall has been followed. The first column gives the molality of Na_2SiO_3 , the second gives p_1 the vapour pressure of water from the solution divided by p° the vapour pressure of pure water. The third column, under N_1/N_2 gives the mol ratio of the two constituents of the solution, i. e. the mol fraction of water divided by the mol fraction of the silicate. The values of N_1/N_2 have been calculated from the molality m by means of the conversion table.¹ If we plot

¹ Lewis and Randall: "Thermodynamics," Appendix 1, p. 609 (1923).

N_1/N_2 against $10 + \log. p_1/p_1^\circ$, we get the difference between the two values of $\log A_2$ (A_2 being the activity of the solute) by obtaining the area under the curve. This quantity is proportional to A_2 , and by taking the fourth root, i. e. assuming ν , the number of ions from complete dissociation of the solute molecule at infinite dilution, equal to 4, and dividing by m , we get a series of values, $k\gamma$, proportional to γ , the activity coefficient.

TABLE II

m	p_1/p_1°	N_1/N_2 Ratio 1:1	$10 + \log p_1/p_1^\circ$	$k\gamma$
1.213	0.955	41.76	9.9800	0.824
0.531	0.973	99.63	9.9881	1.364
0.200	0.988	298.0	9.9948	1.625
0.051	0.996	999.0	9.9983	1.930
Ratio 1:2				
1.0	0.9811	27.4	9.9917	1.0
0.50	0.9872	57.0	9.9944	1.8734
0.25	0.9917	110	9.9964	3.3016
0.10	0.9959	510	9.9982	6.232
0.05	0.9977	999	9.9990	8.824

The values of $k\gamma$ in the last column of Table II give, of course, only comparative values of γ over the molalities quoted, because no measurements of vapour pressure are accurate enough in extremely dilute solution to warrant extrapolation to $\gamma = 1$. However, as will be seen later, when γ is calculated from freezing point measurements, the value of k can be found and hence γ from these vapour pressure calculations can be determined. This is done later on where γ from vapour pressure and from freezing point measurements are compared.

Freezing Point Measurements

Experimental

The ordinary laboratory or Beckmann method was used, as, at first, these freezing point measurements were intended only as a check on the vapour pressure measurements; but when it was discovered that the vapour pressure method was unsatisfactory, except for concentrated solutions, freezing point determinations of all the ratios viz., 2:1, 1:1, 1:2, 1:3, 1:4 were made at concentrations ranging from 0.005 N_w to 2.0 N_w . The usual precautions were taken; the temperature of the cooling bath, was maintained 2-3° C below the observed freezing point, and the amount of supercooling did not generally exceed 0.3° C. The temperatures were read correct to 0.002° C.

Results

Table III contains the results under the headings N_w or weight normality; m , molality, i. e. gm. mol. wt. ($Na_2O \times SiO_2$) per 1000 gms. solvent; Δ , observed lowering in degrees; Δ/m , molecular depression; "i" = $\frac{\Delta}{m \times 1.858}$, i. e.

0.01	0.005	5.60	3.87	3.55	3.22	3.01

Comparison of Vapour Pressure and Freezing Point Results

Before discussing the freezing-point results it is interesting to compare them with those obtained from vapour-pressure measurements.

In Table VI are given the values of "i" obtained from v.p. and F.Pt. measurements for ratios 1:1 and 1:2.

TABLE VI

Weight normality N _w	Molecular depression molal depr. at infin. dil. of ideal subs.	
	Vapour pressures	Freezing points
Ratio 1:1		
2.427	2.08	1.89
1.062	2.46	2.18
0.41	3.36	2.60
0.102	3.73	3.13
Ratio 1:2		
2.00	1.08	1.03
1.00	1.49	1.22
0.50	1.90	1.67
0.20	2.38	2.19
0.10	2.61	2.74

For ratio 1:1 the values from vapour pressure are considerably higher; this is partly accounted for by the difference in temperature (25°) as these results have not been corrected for temperature in the comparison. In ratio 1:2 there is much better agreement. This is probably due to hydrolysis being greater in 1:1 than 1:2, hence the 25° difference in temperature will have more effect in 1:1 than in 1:2.

The agreement between the two methods is on the whole quite satisfactory; this is shown graphically in Fig. 2 where the molecular depression is plotted against the concentration. This graph shows Δ/m from vapour pressure and F.Pt. measurements and also Loomis' results from F.Pt.

Presentation of Results according to the Activity Theory

The accuracy of the freezing point results does not really warrant the calculation of activity coefficients therefrom as Lewis has based his calculation upon the very accurate work in dilute solution made possible by the recent development in freezing point technique due to the work of Hausrath, Bedford, Adams, Richards etc. However, useful information will be gained, but it must be borne in mind that the values for the activity coefficients given below are not claimed to be strictly correct on this account.

FIG. 2

Calculation of Activity Coefficients at 25°C from Freezing Points

The method of calculation given in Lewis and Randall's "Thermodynamics" has been followed.

The question of assigning a value to ν in the equation¹ $j = 1 - \frac{\Delta}{\nu \lambda m}$ for $\text{Na}_2\text{O} \cdot x\text{SiO}_2$ where x is 1, 2, 3, 4 etc. respectively, is a very difficult one. If ν be put equal to three for ratios 1:1, 1:2 and 1:3 quite impossible and absurd values are obtained. In view of the results already obtained for $\frac{\Delta}{m \times 1.858}$, it seems most rational, and cannot be very incorrect, to put ν equal to 4 for 1:1, 1:2, and 1:3 ratios. In order to get comparable values on the same basis ν has been put equal to 4 for the other ratios as well.

¹ Lewis and Randall: "Thermodynamics," Equation 2, p. 342 (1923).

In the following calculations use has been made of the Lewis-Linhart relationship $j = a \beta m$ to determine $\int_0^m -j d(\log m)$ up to $m = 0.01$, by means of the equation $\int_0^{0.01} -j d(\log m) = \frac{-\beta}{2.303\alpha} \cdot (0.01)a$ while for values of m greater than 0.01 the graphical method has been followed for the evaluation of $\int_m^0 -j d(\log m)$.

The calculation of γ for ratio 1:1 follows in Table VII.

TABLE VII

Calculation of γ for $\text{Na}_2\text{O}:\text{SiO}_2$, 1:1, from F.Pts. (assuming $\nu = 4$ ions)

N_w	m	Δ	$j = 1 - \frac{\Delta}{\nu \lambda m}$	$\log j$	$\frac{j}{2.303}$
2.435	1.217	4.290	0.5145	$\bar{1}.7114$	0.2234
1.063	0.531	2.160	0.3108	$\bar{1}.4925$	0.1349
0.204	0.102	0.548	0.2770	$\bar{1}.4425$	0.1203
0.101	0.050	0.291	0.2170	$\bar{1}.3365$	0.0942
0.050	0.025	0.165	0.1118	$\bar{1}.0483$	0.0485
0.020	0.010	0.070	0.0580	$\bar{2}.7634$	0.0251
0.010	0.005	0.036	0.0313	$\bar{2}.4955$	0.0136

From the plot of $\log j$ against $\log m$, $\alpha = 0.086$, $\beta = 3.0$, whence, by means of the equation $\int_0^{0.01} -j d(\log m) = \frac{-\beta}{2.303\alpha} (0.01)a$, values of $\int_0^m -j d(\log m)$ for concentrations 0.005 and 0.01 have been obtained.

m	$\frac{j}{2.303}$	$\int_0^m -j d(\log m)$	$-\log \gamma$	γ
0.005	0.0136	0.0218	0.0354	0.9217
0.010	0.0251	0.0263	0.0514	0.8884

0.050	0.0942	0.1095	0.2037	0.6256
0.102	0.1203	0.1836	0.3039	0.4967
0.531	0.1349	0.4243	0.5582	0.2766
1.217	0.2234	0.5893	0.8127	0.1539

TABLE VIII

Activity Coefficient, γ , from F. Pt. Based on $\nu = 4$, i. e. each molecule gives 4 ions at infinite dilution

m	NaOH	1:1	1:2	1:3	1:4
0.005	0.950	0.922	0.731	0.604	0.412
0.001	0.920	0.888	0.599	0.484	0.342
0.025	0.867	0.778	0.456	0.359	0.244
0.050	0.820	0.626	0.358	0.252	0.171
0.100	0.765	0.497	0.259	0.179	0.109
0.500	0.700	0.280	0.080	0.052	0.029
1.000	0.680	0.192	0.035	0.029	0.015

The values of γ for NaOH above are taken from Harned.¹

These results are plotted in Fig. 3.

¹ J. Am. Chem. Soc., 47, 682 (1925).

Having calculated γ from freezing-points we can now find γ from vapour pressure measurements, where the quantity obtained was $k\gamma$, not γ .

The comparison is shown in Table IX.

FIG. 3

TABLE IX

Comparison of Activity Coefficients calculated from V.P.'s and F.Pt's.

m	γ from V.P.'s	γ From F.Pt's.
Ratio 1:1		
1.219	0.154	0.154
0.531	0.255	0.277
0.200	0.3035	0.329
0.051	0.3555	0.626
Ratio 1:2		
0.10	0.035	0.035
0.50	0.066	0.080
0.25	0.116	0.130
0.10	0.219	0.539
0.05	0.309	0.358

Except in dilute solution ($0.05 = m$, ratio 1:1) where the percentage error in the vapour pressure measurement is large, the agreement is fair.

Discussion of Results

Such a problem, as this, namely of the behaviour and nature of substances in solution, can only be satisfactorily solved when our ideas regarding solutions in general are stabilised. At present the problem of solutions of electrolytes, and more particularly the anomaly of strong electrolytes, is being attacked along two main lines, both having thermodynamic considerations as their basis.

(1) In the first the idea of actual concentration of ions and undissociated molecules is regarded as the fundamental factor in determining the equilibrium between the different species. The conductivity method is regarded as reasonably accurate in determining such concentrations, but since the law of mass action, expressed in such concentration terms is known not to apply, modifications of this expressed by means of empirical coefficients e. g. Storch's equation have been applied with reasonable success.

(2) In the second mode of treatment, the conductivity method is discarded, and instead of the older conception of actual concentration of ions and molecules, a newer treatment correlating various thermodynamic relationships involving the effect of concentration or activity has been applied also with considerable success.

Considering the first method above, there are three assumptions which may be employed for the calculation of the degrees of ionisation,—

(1) The degree of ionisation is correctly given by the conductivity-viscosity ratio.

(2) van't Hoff's law is obeyed by the ions.

(3) van't Hoff's law is obeyed by the undissociated molecules.

Experimental data show that in general only one of these three assumptions can be true in the case of strong electrolytes, the acceptance of any one involves the rejection of the other two.

It has been pointed out by Bates¹ that the mistake is often made of calculating the degree of ionisation from freezing-point data by using the empirical expression of van't Hoff, $P = iRTC$, which implies that assumptions (1) and (2) above are simultaneously true.

However, until such time as the problem of solutions in general is elucidated, we can still derive much valuable information by making use of the earlier ionic theory and its underlying assumptions relating to ideal solutions. This line will be followed now, although the results from the activity standpoint will also be discussed.

Discussion of Results as calculated from the View-Point of the Activity Theory

Necessarily the whole series of results, based as they are on the one set of experimental data, are relatively the same as those observed when the freezing-point measurements are expressed in terms of the ideal ionic theory, but, as is to be expected from the nature of the two theories, the values of γ , the activity coefficient, are lower than the value of α , the degree of ionisation, calculated from conductivity or from the van't Hoff factor " i ".

In considering the above values of γ in Table VIII, it must be borne in mind that they have been calculated, for all the ratios, (not for NaOH where $\nu = 2$) on the assumption that $\nu = 4$, i. e. that the solute molecule gives rise to 4 ions on complete dissociation at infinite dilution.

¹ J. Am. Chem. Soc., 37, 1421 (1915).

The ratio 1:2 is thus very largely dissociated in dilute solution, but very little in concentrated solution; the almost equal values of γ in dilute solution, and the great difference in values of γ in concentrated solution, for Na_2SiO_3 and NaOH being noticeable from figure 3.

In ratio 1:4 the percentage dissociation has fallen considerably over the whole range of concentrations.

FIG. 4

In Fig. 4, γ is plotted against the ratio. As with all the other quantities measured and plotted in this series of investigations of aqueous solutions of sodium silicates, there are changes of direction in the curves at 1:1 and 1:2 for concentrated solutions, and at 1:2 for dilute solutions. At all concentrations the decrease in γ with increasing amounts of SiO_2 is practically linear after ratio 1:2.

The Results as calculated from the Earlier Ionic Theory

Considering Table V, we see that the greater the proportion of Na_2O in the ratio, the greater the value of " i ", i. e. the colloidal content of the solutions decreases with increase of silica. This is brought out in the graphs in Fig. 5 where the molecular depression is plotted against the ratio. As was the case when conductivity, hydroxyl ion concentration and sodium ion concentration were plotted against the ratio, changes of direction in the curves

are again noted at ratios 1:1 and 1:2; at 1:1 in dilute solution and at 1:2 in the more concentrated solutions; while beyond 1:2, Δ/m falls regularly and linearly as the proportion of silica in the ratio increases.

Ratio 1:1

Ratio 1:1 is the definite crystalline salt, sodium metasilicate, Na_2SiO_3 . The value of "*i*" indicates a fairly large degree of hydrolysis or ionisation, even in concentrated solution. In the most dilute solution investigated, 0.01 N_w ,

FIG. 5

the value 3.87 lies between 3, expected if total ionic dissociation took place, and 4, the consequence of total hydrolytic dissociation and total ionisation of the NaOH so formed, assuming in the latter case all the silica to be colloidal and to have no disturbing effect on the other constituents of the solution. If the latter view is correct, and assuming the laws of ideal solution to apply, then

$\frac{3.87}{4} \times 100 = 97\%$ hydrolysis takes place, a value in very close agreement with the figure calculated from conductivity measurements¹ and with the

¹ Harman: J. Phys. Chem., 29, 1155 (1925).

figure assigned by Kohlrausch¹ from conductivity measurements and also by Loomis² from freezing point measurements. However, only 27.8% hydrolysis is found by E. M. F. measurements (Part IV) a value confirmed by Bogue's E. M. F. measurements.³

Thus we have found 27.8% hydrolysis by E. M. F. measurements and 97% hydrolysis from freezing point lowering and from conductivity, assuming in the latter case the laws of ideal solution to hold, which at this concentration, 0.005 m, will not introduce a very serious error, and also assuming all the silica in solution to be colloidal. These two results are quite incompatible, but the assumptions with regard to the laws of ideal solution can in no way cause such a large discrepancy. Of the two values, the 27.8% found by E. M. F. measurements will be the more correct one.

Therefore we can state with certainty that, neither

(1) 27.8% hydrolytic dissociation into $2\text{Na}' + 2\text{OH}' + \text{colloid } \text{H}_2\text{SiO}_3$ alone occurs, as this does not agree with the freezing-point results,

nor (2) is the silica or silicic acid formed, wholly, if at all, colloidal, i. e. SiO_3 ions must exist in the solution, and both hydrolytic and ionic dissociation must take place.

The interaction of sodium metasilicate and water may be represented as follows at very low concentration, where if hydrolysis has taken place in two stages the concentration of HSiO_3' will be negligible:—

From E. M. F. measurements there is 27.8% hydrolytic dissociation at concentration 0.005m (or $N_w = 0.01$). From sodium ion measurements there is 97.5% of the primary reaction

at this concentration. The H_2SiO_3 formed, as indicated above, may be taken as all crystalloidal, which seems justifiable at this low concentration, and be capable of dissociating into H and SiO_3 ions, a reasonable possibility, in spite of the general belief to the contrary, and one which receives so much support from experimental evidence based upon conductivity measurements, transport number experiments, diffusion experiments, apart from the favourable evidence adduced herein, that it appears almost a certainty. Calculating the van't Hoff factor " i " upon this basis and making use of the OH and Na ion concentration, we get " i " = 3.52, whereas " i " from F. Pts. is equal to 3.87.

This is fairly good agreement, considering that it depends on ordinary laboratory freezing point technique, and on two independent sets of E. M. F.

¹ Z. physik. Chem., 12, 773 (1893).

² Wied. Ann., 60, 531 (1897).

³ J. Am. Chem. Soc., 42, 2575 (1920).

measurements, and it not only supports the view that both hydrolytic and ionic dissociation take place but that a fairly correct percentage value has been obtained for both these dissociations.

Let us consider almost complete hydrolysis into NaOH and colloidal H_2SiO_3 , according to the theory put forward by Kohlrausch¹ and by Loomis,² the extent of such hydrolysis, to be determined by the concentration of sodium ions,³ but assuming the OH ions to be adsorbed to a large extent by the colloidal silica so that the actual OH ion concentration agrees with the percentage hydrolysis found by E. M. F. measurements. On this basis, for concentration $N_w = 0.01$, i. e. 0.005 m, " i " = 2.53 , whereas from F. Pt. measurements " i " is 3.87 . This non-agreement, clearly outside the bounds of experimental error, appears to afford definite proof against OH ion adsorption.

Ratio 1:2

Here there are three possibilities:—

- (1) definite salt NaHSiO_3
- (2) definite salt $\text{Na}_2\text{Si}_2\text{O}_5$
- (3) aggregates or micelles.

(1) *definite salt NaHSiO_3 .*

Following the same reasoning as already given for ratio 1:1, and taking the values found for OH ion and Na ion concentrations, communicated in two previous papers, as giving the percentage hydrolytic and percentage ionic dissociation respectively, we get at concentration $m = 0.05$, since percentage hydrolysis equals 0.051 and percentage ionisation equals 0.60 , " i " = 3.34 , taking into account that the concentrations expressed herein are in terms of $\text{Na}_2\text{O} \cdot 2\text{SiO}_2$.

(2) *definite salt $\text{Na}_2\text{Si}_2\text{O}_5$.*

For the same concentration, 0.005 m, where percentage hydrolysis equals 0.051 and percentage ionisation equals 0.60 , " i " = 2.5 .

Since " i " from F. Pt. equals 3.50 , on this evidence alone one would say that it is extremely probable that the salt NaHSiO_3 exists in solution.

¹ Z. physik. Chem., 12, 773 (1893).

² Wied. Ann., 60, 531 (1897).

³ Harman: J. Phys. Chem., 30, 922 (1926).

(3) *aggregates or micelles.*

Several suggestions could be put forward to explain the values of "*i*" obtained but as all of these would be largely hypothetical, it seems better to defer this for the moment, except to state that from transport number experiments we know that one proportion of SiO_2 carries one charge of electricity and so the ion is not the simple ion SiO_3 , and from freezing point measurements the existence of the salt NaHSiO_3 seems most probable.

Thus for ratio 1:2 the existence of the acid metasilicate NaHSiO_3 agrees very well with all the experimental data so far given.

Ratios 1:3 and 1:4

When we consider ratios 1:3 and 1:4 and bear in mind the result of transport-number experiments at moderate concentrations, where it was found probable that there were three and four proportions of SiO_2 respectively per divalent charge we admit two possibilities:—

(1) definite salts,

ionising to give sodium and silicate ions of composition $(3\text{SiO}_2\text{aq})$ and $(4\text{SiO}_2\text{aq.})$

(2) Aggregates or micelles of the composition $[\text{m} \cdot \text{SiO}_3 \cdot \text{n} \cdot \text{SiO}_2\text{aq.}]^{m-}$ where $(\text{m} + \text{n})/\text{m}$ equals the ratio, or an aggregate containing amongst other constituents a number of SiO_2 equivalents approximately equal to the ratio per divalent charge.

Let us consider these two possibilities.

(1) *Definite salts.*

Calculating "*i*" as before for concentration $\text{m} = 0.05$, since hydrolysis is practically negligible and the percentage ionisations as given by Na ion concentration are 0.70 and 0.55 respectively for ratios 1:3 and 1:4 we get

ratio	" <i>i</i> " calculated	" <i>i</i> " from F. Pts.
1:3	2.40	3.22
1:4	2.10	3.00

Hence the existence of definite salts so ionising seems very unlikely.

(2) *Aggregate or micelle formation.*

In very concentrated solution the silicate probably exists as a very complex aggregate, which not only breaks up on dilution but also gives rise to Na^+ and SiO_3^{2-} or other simple silicate ions, these latter coalescing to form ionic micelles. Only on some such theory can the results from conductivity, transport numbers, hydroxyl and sodium ion concentrations, and freezing points be explained.

In solutions of these higher ratios the OH ion concentration is practically negligible, especially in concentrated solutions, and the sodium ion concentration as found by E. M. F. measurements accounts for only a small fraction of the total crystalloidal content as calculated from the lowering of the freezing point.

For example, at concentration $N_w = 0.01$, the normality due to Na ions is 0.011, while the total normality as found from freezing-points is 0.03, thus leaving 0.019 N to be accounted for either by the silica present, or by some form of undissociated silicate, or both.

In more concentrated solutions, e. g. 0.1 N_w , 1:4 ratio, where the total normality is found to be 0.23, the normality due to the Na ions is only 0.05.

It is not proposed to go into this question in this paper, but it is hoped to give a rational complete theory shortly when all the experimental data obtained have been published. It will be sufficient to indicate here that at present it appears that the ratios higher than 1:2 are not definite salts giving definitely determinable silicate ions in solution. Rather, having regard to the fact that the value for "i" is abnormally low in concentrated solutions and exceptionally high in dilute solutions, and to the results of transport number experiments, ionic micelles of the composition $(m.SiO_3.n.SiO_2.aq.)^{m--}$ appear to be present, where $m + n/m$ equals the ratio; and the following equilibria exist,—

and

Evidence for equation (1) is also obtained from transport number experiments, while in a later paper it will be shown that equation (2) is not only true but takes place to a much greater extent than commonly supposed even in moderately concentrated solutions.

Until further work is done with the specific purpose in view of determining the exact constitution of the silicate in these high ratios i. e. of proving conclusively that it is or is not the SiO_3 ion which is here formed in dilute solution, and until more exact knowledge is gained concerning H_2SiO_3 itself, we can only state that micelle formation offers the best explanation of the experimental data given herein,

It must be emphasized that the foregoing suggestions of the existence of aggregates and ionic micelle are only tentative.

Summary

(1) Measurements of the lowering of vapour-pressure have been made by a dynamic method, for ratios $Na_2O : SiO_2$, 1:1 and 1:2 over a concentration range 0.1 — 2.5 N_w , and the results expressed in terms of the earlier ionic theory and also in terms of the more recent activity theory.

(2) Lowering of freezing-points by the Beckmann laboratory method have been found for ratios 2:1, 1:1, 1:2, 1:3 and 1:4 over a concentration range 0.01 — 2.0 N_w , and the results expressed in terms of the van't Hoff factor "i" and in terms of the activity theory.

(3) The results from V. P. and from F. Pts. are in fair agreement.

(4) Ratios 2:1 and 1:1, and to less degree 1:2, exhibit a high degree of osmotic activity, more especially in dilute solution. Ratios 1:3 and 1:4 show an abnormally low osmotic activity in concentrated solution but unexpectedly high in dilute solution.

(5) From the results it appears that ratio 1:1 is the salt Na_2SiO_3 undergoing both hydrolytic and ionic dissociation giving rise to Na' , OH' and SiO_3'' ions and H_2SiO_3 , most of the latter being crystalloidal. Na_2SiO_3 is practically completely dissociated in dilute solution but only 27.8% hydrolytically. Ratio 1:2 is the definite salt NaHSiO_3 , behaving like Na_2SiO_3 and giving rise to Na' , OH' and HSiO_3' ions and H_2SiO_3 . There is 0.60% dissociation at concentration 0.005 m but only 0.05% hydrolytic dissociation. The results from ratios 1:3 and 1:4 are not in accord with the view that these ratios are definite salts but agree well with the existence of complex aggregates in concentrated solution and of ionic micelle of the composition $[\text{m. SiO}_3.n .\text{SiO}_2\text{aq.}]^{m-}$ where $m + n/m = \text{ratio}$; the following equilibria also existing

I wish to thank the Commissioners of the 1851 Exhibition for a Scholarship which has enabled me to carry out this investigation, and to express my gratitude to Professor Donnan, at whose suggestion this work was undertaken, for his constant kindly interest and advice.

THE THERMAL DECOMPOSITION OF NITROSYL CHLORIDE¹

BY H. AUSTIN TAYLOR AND ROY. R. DENSLOW

The purpose of the investigation reported here was to determine the effect of surface on the reaction in question. Enough has been written already to emphasise the difference between purely gas reactions and surface reactions. Even reactions to which a catalyst has not been intentionally added may be influenced by the walls of the containing vessel, probably due, as pointed out by Norrish², to the polar nature of glass which is so frequently used for containers. Not all reactions however, are catalytic in nature necessarily. Phosphorus trichloride and chlorine, both thoroughly dried, react at a low temperature in a wax vessel, at a rate that it is impossible to measure³. A large number of gas reactions have been studied by Hinshelwood and others⁴ to determine their mechanism in the presence of specific catalysts. Some have been found to proceed both in the gas phase and on the surface of the catalyst or container, while a few have been found to be truly homogeneous. In a recent paper in which the well-known thermal decomposition of hydrogen iodide⁵ was shown to be influenced by glass and to proceed only in part in the gas phase, it was pointed out that "attempts at a theoretical evaluation of bimolecular reaction velocities have made use in many cases of data of reactions which were assumed to be homogeneous gas reactions but which are now being shown not so." It was for this reason that the present work was undertaken.

As nitrosyl chloride is a somewhat unfamiliar substance, it may be of interest to mention briefly some of its more important properties. It is probably formed to some extent in concentrated aqua regia, but as it is easily decomposed by water, the quantity can not be very large. It is a yellowish gas, rather resembling nitrogen peroxide in appearance and having absorption bands in the orange and green⁶. The critical temperature is 163-164°C and it can be liquefied at -5.8° to a blood-red liquid, which by cooling to -61.5°C⁷ can be frozen to a red solid resembling chromic oxide in appearance. Several methods of formation are given in the literature. Two of these are more frequently used than the others; in fact most of the methods are modifications of these. The first is that of Tilden⁸, and Girard and Pabst⁹ which consists

in heating nitrosyl sulphuric acid (lead chamber crystals) with dry sodium chloride. The second is that of Gay Lussac¹ which consists in the direct combination of chlorine and nitric oxide, the reaction being represented by the equation:

When prepared by the first method it is more likely to be contaminated by nitrogen peroxide. It will be noted that there is a rather close analogy between the gas and nitrogen peroxide. The latter can in fact be considered as nitrosyl nitrate. In a recent paper W. A. Noyes² reports that no binary compound of nitrogen and chlorine in which chlorine is a negative element has so far been found. In other words it seems to be impossible to replace the oxygen in nitrosyl chloride by two atoms of chlorine. Considerable work³ has been done to determine if any other compounds of the three elements exist such for example as NOCl_2 , NOCl_3 , NO_2Cl etc. but there seems to be no unequivocal evidence for the existence of any of these with the possible exception of NOCl_2 , which according to Trautz⁴ is formed as an intermediate product when chlorine and nitric oxide react, but which decomposes at a comparatively low temperature. It may be mentioned also that nitric oxide is fairly soluble in liquid nitrosyl chloride but is liberated when the latter is frozen. The most important chemical property of nitrosyl chloride to be remembered in working with it, is its immediate reaction with water to form hydrochloric and nitrous acids, the latter then decomposing in the usual way.

The gas has been used by Guye⁵ and others at Geneva in atomic weight work, and in their papers considerable information will be found about the details of preparation and purification as well as the physical properties. Trautz and his co-workers have studied the energetics and kinetics of the combination reaction. From the data of Trautz and Wachenheim⁶, Lewis and Randall⁷ have calculated the free energy change for the reaction of combination between 500° and 750°K

as

$$\Delta F = -9100 + 14.3 T$$

From this it will be seen that ΔF will be negative for the combination reaction at low temperatures, but will change sign as the temperature is raised, at about 636°K in fact. If we consider the decomposition of nitrosyl chloride into nitric oxide and chlorine, it is evident that we have a substance which is

⁷ "Thermodynamics" (1923).

thermodynamically stable at low temperatures and unstable at high temperatures. If we consider the breaking down into its elements the reverse is true on account of the thermodynamic instability of nitric oxide.

The most accurate measurements of the kinetics of the combination at room temperatures are those of Kiss¹ in his studies of the catalytic effects of bromine and nitrogen peroxide. He agrees with Trautz in stating that the surface of the container has but little effect if any.

Experimental

Nitrosyl chloride was prepared by the method of Gay Lussac, by treating liquid chlorine with nitric oxide in excess. The chlorine was prepared in the usual manner by the action between concentrated hydrochloric acid and potassium permanganate. The gas was passed through water to remove any hydrogen chloride and the water then removed by passing through two wash bottles containing concentrated sulphuric acid and finally through about 15 cm. of phosphorus pentoxide and glass wool. The nitric oxide was made by Winkler's method², namely, the reaction between nitrous and hydriodic acids. To a mixture of potassium iodide and sodium nitrite covered with a little water, sulphuric acid (approximately 50 percent) was added. A rapid reaction takes place with the formation of nitric oxide and iodine. The gas was passed over a moist red phosphorus to remove any volatilised iodine, and then through sodium hydroxide solution to remove the hydrogen iodide formed and also to remove any nitrogen peroxide which might be present. The gas was dried in the same manner as was the chlorine.

The apparatus used for the preparation of the gas was similar to the one used by Trautz and Gerwig³ in their studies of the vapor pressure of nitrosyl chloride. A suitable amount of chlorine (about 30 grams) was liquefied in the apparatus with a mixture of solid carbon dioxide and toluene. The latter which was used by Trautz, is preferable to ether as it is much less volatile. Then, taking precautions to prevent it becoming admixed with air nitric oxide was passed into the chlorine. After a short time the liquid changed from its original yellowish green color to the characteristic red of nitrosyl chloride and the color became deeper as the reaction proceeded. Care was taken to ensure that an excess of nitric acid had been used, for otherwise the product contains more than the theoretical amount of chlorine, while the excess nitric oxide can be removed by freezing and evacuating. The nitrosyl chloride so obtained was distilled twice, the second time directly into the vessel used as a reservoir throughout the experiments. During the first distillation it was passed through a tube heated to 150°C., this precaution being suggested by Trautz to decompose any dichloride which might be present. It is necessary to prepare the gas in an all-glass apparatus on account of the corrosive action on rubber.

² Moser: Z. anal. Chem., **50**, 401 (1911).

³ Z. anorg. Chem., **134**, 409 (1924).

The reaction tube which actually passed through the furnace was made of quartz and was sealed to the remainder of the apparatus, which was of Pyrex, with alundum cement and water glass. The furnace was an ordinary "multiple-unit" furnace, the ends of which were closed with thick asbestos board, with holes for the reaction tube and the thermocouple of a Hoskins pyrometer.

It was planned to study the decomposition by a dynamic method similar to that used by Taylor in the study of the decomposition of hydrogen iodide. In that work the condensed gas maintained at constant temperature, $0^{\circ}\text{C}.$, was forced through a capillary under the constant pressure developed in the holder. The gas thus flowed at a constant rate through the reaction tube. The effluent gases were absorbed and analysed.

It was necessary, therefore to devise a method for the analysis of a mixture of nitrosyl chloride, chlorine, and nitric oxide; or if the gases were to come in contact with water, a mixture of chlorine or hypochlorous acid, nitric oxide, hydrochloric acid and nitrous acid, or the decomposition products of the latter, nitric oxide and nitrogen peroxide. This is a rather unusual mixture and a little consideration will show that none of the more obvious methods could be used. Potassium iodide solution for instance, would be affected not only by the chlorine, but also by the nitrous acid. Acidimetric methods could not be used, for acids are present from both the reactant and the resultants, not to mention the disturbing effect that the hypochlorous acid might have on any indicator. An attempt was first made to use the following procedure: to calibrate the capillary by allowing nitrosyl chloride to pass through it directly into water and to determine the chloride present by gravimetric analysis with silver nitrate. This would give a measure of the total undecomposed gas passing through the system in any specified time. As nitric oxide is so slightly soluble, it was thought that if the mixture were passed into a solution of a base, everything would be dissolved except the nitric oxide, which could be collected and measured in a eudiometer tube. Having then the total nitrosyl chloride and the nitric oxide, the composition of the mixture would be known. It was found however, that after the nitrosyl chloride had been carefully freed from dissolved nitric oxide, no measurable quantities of nitric oxide were obtained. The same results were recorded even when the gas delivery tube was surrounded by a supplementary electric heater and when the furnace itself was heated to a high temperature. This would signify either that such a small quantity had been formed that it was all dissolved, or that it had completely recombined with the chlorine before reaching the water.

Sudborough and Miller¹, by determining the vapor density, found that the dissociation of nitrosyl chloride became evident at $700^{\circ}\text{C}.$, giving data as follows:

Temperature	Per Cent dissociated	Temperature	Per Cent dissociated
784°C	5.34	928	25.17
796	8.22	968	39.19
815	10.64	985	41.85

¹ J. Chem. Soc., 59, 271 (1891).

If these figures could be considered reliable, it seemed likely that the recombination was the explanation of the result, and this was confirmed in the later work. For this reason another method of analysis was used, which, while having some disadvantages, seemed to be the only one available.

The total amount of nitrosyl chloride was determined in the same way as before. A standard solution of sodium arsenite, about 0.05N, free from chloride was prepared in the usual way by dissolving arsenious oxide in sodium hydroxide, neutralising the solution with sulphuric acid and then adding an excess of sodium bicarbonate to act as a buffer. This was standardised against an iodine solution of about the same concentration, which in turn was standardised against pure arsenious oxide.

A known quantity of the arsenite solution was measured in a calibrated pipette. To this, water was added and the container placed under the delivery tube for a definite time, usually ten minutes. At the expiration of that time the delivery tube was washed off and the unused arsenite titrated with the iodine solution. In this manner a measure of the free chlorine was obtained, which in turn gave a measure of the nitrosyl chloride decomposed. It was found by passing the unheated gas into the arsenite solution that the nitrous acid and other substances present were without influence on the sodium arsenite.

In order to reduce the recombination, the furnace was placed in an upright position, with the quartz reaction tube extending from it only far enough to reach the surface of the liquid in the absorbing vessel. Arrangements were made for washing off the end of the tube so that the timing of the experiment could be done with an accuracy of about one per cent. A certain amount of decomposition was now measurable, but it was small, and there was considerable deviation between the results of experiments made under the same conditions, even when the capillary was so small that only a few milligrams of gas were going through it per minute.

A few experiments were made to determine the effect of mixing oxygen with the gas before it reached the furnace. The oxygen was allowed to flow at such a rate (about 8.5 cc. per minute) that the mixture of the two gases was practically colorless before entering the furnace. At the outlet above the level of the absorbing liquid, the color was distinctly brown, due either to nitrosyl chloride, nitrogen peroxide or both. Kiss has shown that nitrogen peroxide catalyses the formation of nitrosyl chloride. It should therefore catalyse the decomposition, but it is hardly likely that that is the explanation of the effect, because at the high temperature of the furnace (700-1000°C) nitrogen peroxide is decomposed. It is probable that the oxygen lessens the time of contact of the nitrosyl chloride with the furnace, and also cuts down on the interval between leaving the furnace and reaching the absorbing liquid. The distance to be covered here was only a few centimeters but for a comparatively fast reaction like the recombination of the chlorine and nitric oxide it would be sufficiently long to have a marked effect. It must also be noted that the oxygen and chlorine would be competing for the nitric oxide and the velocities of these two reactions are about the same. It was found

that a decomposition of approximately five per cent per minute in the furnace was obtained and that this was more than doubled by doubling the rate of flow of the oxygen.

Because of the complicating factors mentioned above, it was decided to substitute dry nitrogen for oxygen as a diluent. It was mixed with the nitrosyl chloride, as in the case of the oxygen, by a side tube sealed to the apparatus between the reservoir of liquefied gas and the furnace. Its rate of flow was regulated by a capillary in one of the arms of a T tube, the other arm being connected with a cylinder of compressed nitrogen, and the upright part extending down into a cylinder of concentrated sulphuric acid. By observing the head of acid corresponding with a measured volume of nitrogen, it was possible to determine the rate of flow in any experiment with sufficient accuracy. With the capillary used, it was possible to obtain rates of flow up to about 22 cc. per minute. This is about ten times the rate of flow of the nitrosyl chloride.

In the final experiments the quantity of total nitrosyl chloride going through the system was determined frequently by absorbing the gases in sodium arsenite solution, adding silver nitrate and finally nitric acid to dissolve the silver arsenite formed along with the silver chloride. The silver chloride was filtered through a Gooch crucible.

The percentage decomposition per minute in the furnace was calculated by means of the following expression:

$$\text{Percent decomp.} = \frac{100 \text{ a } v \text{ T (NOCl) (1000) (298) W} + (2.9919) (273) (\text{AgCl}) \text{ mg}}{(2.9919) (273) (298) (\text{NOCl}) \text{ m F W}}$$

where the symbols have the following significance:

a No. grams of NOCl equivalent to 1 cc. of I₂ solution.

v Vol. of I₂ used to titrate excess sodium arsenite.

T Absolute Temperature of furnace

W No. of grams of AgCl obtained in m minutes

m Time of experiment in minutes (10)

g No. of cc. of N₂ at 298°K passing per minute

F Volume of tube in furnace (58 cc.)

(NOCl) and (AgCl) represent the molecular weights of the two substances and 2.9919 grams is the weight of one liter of the former at standard conditions.

The results obtained with the empty tube are given in Table I.

It was originally intended to allow the reaction to proceed in the presence of powdered glass or silica, but this proved to be impracticable in view of the position of the furnace and the upright reaction tube. To test the effect of surface, pieces of broken quartz were placed in the tube and held in position by a plug of asbestos. The increased area thus obtained cannot be estimated with any degree of accuracy. The decrease in volume of the free space was about 15 cc. and the quartz pieces were distributed from the top to the bottom of the reaction tube. The results shown in the following table are seen to be quite comparable, within the limits of experimental error, with the previous results.

TABLE I

W	v	g	T	$10^4/T$	log % decomp.	% decomp.
0.0596	0.22	18.0	971	10.30	0.4680	2.94

0.0690	.32	18.5	1123	8.904	.6452	4.42

This is shown also by some experiments conducted with a much slower rate of flow of nitrogen, namely 6 or 7 cc. per minute. At 1019°K , decompositions of 0.99 and 0.95 per cent were obtained with the empty tube and the other respectively.

0.0854	.36	19.0	1123	8.904	.7506	5.64

The obvious lack of agreement in the results recorded above calls for an investigation of the errors to which the percentage decomposition as calculated from the previous expression is affected by the variables involved. It is found in general that the percentage error in the calculated result caused by a variation of any one of the quantities a , v , T , m , g , and F , is either the same or approximately the same, as the percentage error in the value of that quantity. In no case is the error multiplied. The most serious error occurs in the evaluation of the number of grams of gas decomposed, which is obtained from v , the difference between two measured volumes of iodine solution. Since it is the rate and not the equilibrium that we are measuring, it is evident that the amount of free chlorine will be small and consequently the

difference in volume of iodine solutions will be small also. It is estimated that the error in v may be as high as 12.0%. This could doubtless have been reduced somewhat by the use of weight burettes, but in the cases of slight decomposition, would still have remained high.

Discussion of Results

If it be assumed, as the work of Trautz leads us to believe, that the decomposition takes place according to a bimolecular law, the velocities can be calculated from the ordinary expression:

$$k = 1/t \cdot x/a(a-x)$$

FIG. 1

by suitable substitution of the foregoing data. In the experiment at 1020°K. the following numerical result was obtained:

$$k = 5.0 \times 10^{10} \text{ cc. per mole per min.}$$

It has been pointed out above that the reverse reaction is taking place also at a rapid rate. This would raise doubt as to the validity of using the ordinary bimolecular equation. The expression for the rate of the decomposition, taking into consideration the reverse reaction, would be:

$$dx/dt = k_1(a-x)^2 - k_2(x^2/2)$$

where x is the amount of nitrosyl chloride decomposed in t minutes from an original concentration of nitrosyl chloride a . This equation cannot be readily integrated. It was decided therefore to plot the logarithm of the percentage decomposition against the reciprocal of the absolute temperature instead of the logarithm of the bimolecular constant. On account of the comparative inaccuracy of the results the mean values at the same temperature have been used. This will be seen to give over a wide range a straight line with a small slope, Fig. 1. The decompositions of the gas in the presence of the broken quartz are seen to lie on the same line.

From the slope of the line we can make an approximation as to the heat of activation as well as the temperature coefficient. The latter has a value of about 1.025, and the former is found to be in the neighborhood of 6000 calories. The results would seem to indicate too, that the activation was not caused by the quartz, although the high temperatures necessary for reaction would probably preclude the possibility of any adsorption of nitrosyl chloride by the quartz.

If such be the case we have here another gas reaction to which the theories of activation in homogeneous systems may be applied. To take the simple

radiation theory an energy of activation of 6000 calories at these temperatures would correspond to a wave length of 4.769μ . This wave length so far as is known does not correspond with any absorption band in the spectrum of nitrosyl chloride.

Summary

1. The decomposition of nitrosyl chloride has been studied by a dynamic method between the temperatures 700° and 900°C . the rapidity of the reverse reaction being overcome by increasing the rate of flow of the gas by diluting with nitrogen.
2. The effect of an increased surface of reaction has been studied and shown to be negligible within the limits of experimental error.
3. The temperature coefficient and energy of activation appear to have values of 1.025 and 6000 calories respectively.

New York, N. Y.

THE APPARENT VISCOSITY OF COLLOIDAL SOLUTIONS

BY EMIL HATSCHEK

In a recent paper¹ McBain advances a conception of the structure of sols of nitro cotton which he summarizes as follows: "This conception shows clearly how apparent viscosity of various solutions of nitro cotton is to be explained. It is due to the presence of loose ramifying aggregates of micelles. The best solvents are those in which dismemberment proceeds furthest through solvation at the various points of affinity. Poorer solvents are those in which dismemberment is less complete and the apparent viscosity therefore much higher." McBain further assumes a general connexion between this structure and the elasticity of sols: "I venture to suggest that the presence of elasticity in a colloidal solution is a specific positive test for the presence of ramifying aggregates."

The term "elasticity" in this connexion can mean only elasticity towards shear or, to employ the usual term, rigidity (absent in normal liquids), since volume elasticity, i. e. resistance to a reduction of volume, is a common property of all liquids, whether sols or homogeneous.

The experimental data, on which these conceptions are partly based, more particularly the results of numerous viscosity determinations carried out in the ordinary capillary viscometer, are given in a paper by McBain, C. E. Harvey and L. E. Smith.² The summary of this paper also postulates a structure consisting of ramifying aggregates and adds: "The above theory, if correct, should be applicable throughout the whole subject of colloids."

Since these views naturally command attention, and since they have been quoted as if they were fully established,³ it seems desirable to examine what the evidence for them actually is. There appears to be no record of such aggregates having been observed ultramicroscopically in nitro cotton sols, nor in many other highly viscous sols, like those of rubber, dyes like Cotton Yellow, or of gelatin and agar at suitable temperatures. The value of this negative evidence must, of course, not be overrated, since most sols of this type do not show differentiated particles at all. All the more importance must therefore be attached to observations on a sol, the particles of which *can* be made visible, *exhibiting high viscosity culminating even in gelation without aggregation or even mutual approach of the particles*. The aged ferric hydroxide sols investigated by E. Schalek and A. Szegvari⁴ are the case in point. These sols, on the addition of electrolytes, set to gels, which can be transformed back into sols by mere shaking; the sols thus formed gelate again spontaneously, and this cycle can be repeated indefinitely, the gelation time remaining approxi-

¹ J. Phys. Chem., 30, 239 (1926).

² J. Phys. Chem., 30, 312 (1926).

³ Bancroft: J. Phys. Chem., 30, 1152 (1926).

⁴ Kolloid-Z., 33, 326 (1923).

mately constant. The particles are made visible by using Szegevari's "azimuth stop" with the cardioid condenser and, not being spherical, are seen only in definite orientations towards the axis of illumination and that of the microscope, so that they scintillate while in Brownian motion. When the particles come to rest, this scintillation ceases, and the process of gelation can therefore be followed with the ultramicroscope, as well as the process of liquefaction or re-solution, which pressure on the cover glass is sufficient to produce. The authors describe their observations as follows:

"If such a preparation is observed for a period of some length (which is of the same order as the time of gelation measured macroscopically), we can observe that *the scintillations gradually become feebler*, until after some time all visible movement has ceased. We are therefore observing the solidified gel. What seems most remarkable is that, apart from the cessation of the motion, *no difference at all compared with the sol state can be perceived*. There is, more especially, no trace of any formation of secondary particles; *the particles are the same mean distance from one another as in the liquid state*." (NB. The italics throughout are those of the original).

This instance, in which the optical evidence seems complete, appears sufficient to demonstrate that gelation, and *a fortiori* the great rise in viscosity which precedes it, is possible without the formation of any aggregates whatever, whether ramifying or otherwise. The ferric hydroxide sol is quite generally considered to be hydrated and though it is not strictly a neutral sol, the latter point is immaterial in view of McBain's conditional claim that his conception is applicable to all colloids.

Schalek and Szegevari do not attempt to explain how gelation comes about without approach of the particles, nor will such an attempt be made here. It may however be worth mentioning that in a sol with optical properties very similar to those of the ferric hydroxide sol, viz. the well-known vanadium pentoxide sol, ultramicroscopic observation (by Zocher¹) leaves no doubt that during coagulation the (rodlike) particles actually aggregate with mutual contact. This sol does not form gels, and the slow increase in viscosity during ageing is not accompanied by an aggregation.

Schalek and Szegevari have also determined, in the Hess pressure viscometer, the viscosity of their ferric hydroxide sol at different shear gradients and have found it to vary with the latter. They discuss the question whether such a variation is necessarily evidence of rigidity; in this connexion it is significant that Freundlich and Seifriz,² using the fairly conclusive method of micromanipulation, could not detect elasticity in a similar sol 10 years old.

A short reference to the rigidity of sols is made necessary by McBain's suggestion, quoted above, that "the presence of elasticity in a colloidal solution is a specific positive test for the presence of ramifying aggregates." Since McBain assumes this structure in nitro cotton sols, the inference is reasonable, or indeed inevitable, that he is convinced of having demonstrated elastic properties in these systems.

¹ Z. physik. Chem., 98, 293 (1921).

² Z. physik. Chem., 104, 233 (1923).

It does not appear from his paper on what evidence he relies. If it should be the variation of viscosity with shear gradient, he would be in the excellent company of authors like Freundlich and his collaborators,¹ who have investigated a large number of sols by the only theoretically correct method, viz. in a correctly designed concentric cylinder apparatus. Freundlich indeed has explicitly raised the question whether variable viscosity is conceivable apart from elastic properties. This question seems to be completely answered by the results obtained in 1916 by Edith Humphrey and E. Hatschek,² who demonstrated in the cylinder apparatus that *suspensions of rigid particles in a normal liquid* exhibited the same variation of viscosity with shear gradient as do lyophil sols. This result has been very generally overlooked, and the present writer and R. S. Jane have accordingly repeated and extended these determinations and have re-published them recently.³

McBain, indeed, quotes the earlier paper by Humphrey and Hatschek. If he relies on variable viscosity as evidence of elasticity their result places him in an obvious dilemma: he can either explain it by assuming that a few per cent of starch grains in an organic liquid impart rigidity to it, in which case rigidity is possible without ramifying aggregates; or he can admit that variable viscosity may be due to other causes besides rigidity, in which case the variable viscosity of nitro cotton sols is obviously no proof that they possess elastic properties.

As already emphasized, McBain does not anywhere explain how elastic properties in nitro cotton sols are demonstrated. In the absence of such data it seems difficult to accept his postulated connexion between a hypothetical structure and unproved elastic properties as evidence of either.

It may be added that the existence of rigidity in liquids can be demonstrated, and even the modulus be determined, by strict physical methods, so that there is no reason for relying on questionable inferences. The elegant method developed by T. Schwedoff in 1889 has recently been used by E. Hatschek and R. S. Jane⁴ for an extensive investigation of typical sols, which incidentally brings out the enormous difficulty of establishing any connexion between viscosity and even a strictly defined elastic constant.

McBain advances a number of chemical considerations in support of his hypothesis of ramifying aggregates, among them one referring to a substance with which the present writer is rather more familiar than with nitro cotton: "Unpublished work by Salmon and Manning explains the action of urea in depriving gelatin of its power to set to a jelly, combination of the urea with the gelatin replacing the usual linking up of the terminal amino and carboxyl groups." A great many substances, e. g. potassium iodide, ammonium thiocyanate, calcium chloride, sodium salicylate, etc., in suitable concentrations also prevent the setting of gelatin, and presumably do so without chemical combination, as the sols again set to jellies when the salts are dialysed

¹ Freundlich, Neukircher and Zocher: *Kolloid-Z.*, **38**, 43, 48 (1926).

² *Proc. Phys. Soc. London*, **28**, 274 (1916).

³ *Kolloid-Z.*, **40**, 53 (1926).

⁴ *Kolloid-Z.*, **39**, 300 (1926).

out. An effect on the linking of the terminal groups of gelatin becomes even more improbable, when it is remembered that potassium iodide and ammonium thiocyanate have exactly the same effect on sols of agar, with a totally different constitution. The combination of urea with gelatin, to put the matter plainly, is no longer gelatin, and the fact that this new body does not gelate cannot throw any light on the mechanism of gelation in unaltered gelatin.

While it is thus difficult to see any positive evidence of the existence of ramifying aggregates, and while high viscosity and even gelation are demonstrably possible without this structure, the hypothesis would still be entitled to consideration on the ground that it explained the high viscosity of sols like those of nitro cotton (or, say, of rubber) much better than any other. And of course McBain takes the view that it does so. He first insists on the inadequacy of the Einstein formula, which seems a little irrelevant, as no competent worker has ever applied it to sols exhibiting 50 to 100 times the viscosity of the dispersion medium, and conforming in no single particular to the assumptions on which the formula is based.

McBain further criticizes the present writer's view which, very briefly, is that the disperse phase in the sols under discussion consists of aggregates that have taken up a great part of the dispersion medium by a process analogous to that of swelling in bulk and that these swollen aggregates or micellae are liquid or easily deformable. The view (though this is immaterial) is practically that of Naegeli, which McBain has advocated since about 1920; the only additional assumption is that of easy deformability. Whether the process by which the micellae take up liquid is "true" solvation is quite immaterial. If the micellae are assumed of equal size and simple shape, e. g. tending to be spherical but so crowded that they have to be polyhedral, the cube root formula quoted by McBain can be deduced, which is more conveniently written:

$$\eta' = \eta \frac{1}{1 - \sqrt[3]{\varphi}}$$

where φ is the ratio: volume of disperse phase to total volume.

While this formula—necessarily—also assumes a structure, it is the simplest conceivable. Experiment has shown that the formula is even a little better than might be expected, since, as McBain points out, it expresses the viscosity of suspensions of red blood corpuscles with considerable accuracy, although these are very much larger than colloid particles, are not liquid but elastically deformable, and finally are not polyhedral, but of a peculiar shape which might give pause even to an enterprising mathematician.

It is obvious that, as φ approaches unity, the viscosity grows very rapidly; conversely, in a system with high viscosity the disperse phase must occupy practically the whole volume or, in other words, must have taken in practically the whole of the dispersion medium. McBain considers this view quite

untenable and disposes of it, as far as nitro cotton is concerned, by the statement: "We know from direct sorption experiments that nitro cotton does not take up more than its own weight of solvent."

While, of course, fully accepting this statement, one must regret that no details whatever are given of experiments to which such crucial importance is attached. To appreciate what bearing on the point at issue they really have, it would be necessary to know whether they were made in saturated vapour or in liquid solvent, and the nature of the latter; more particularly whether it was one in which nitro cotton ultimately disperses, e. g. acetone, or one in which it merely swells, e. g. alcohol at ordinary temperature. In the first alternative it would be essential to know how the sorption equilibrium was defined, and in the second the question arises how far the results are relevant at all, i. e. how they could bear on complete dispersion in another liquid.

Even in the absence of such information the argument from sorption can be disposed of by showing that:

1. Sorption experiments can give no clue to the magnitude of solvation and its variation with concentration;
2. There are plenty of substances which take up quite enough solvent to account for the volume of disperse phase required by the formula, and
3. In one, carefully investigated case a definite parallelism exists between the amounts taken up by the gel in swelling in different solvents, and the solvation or imbibition calculated from the viscosities of sols in the same solvents.

1. A case of true hydration will serve to prove this thesis. A. W. Porter¹ has calculated from Morse's and from Lord Berkeley's data on osmotic pressure the hydration numbers, i. e. the number of molecules of water associated with one molecule of sugar and thus withdrawn from the solvent. The values for two concentrations, (weight-molar) used by both investigators are given in Table I; Morse's cover a temperature range from 0° to 60°, while Berkeley's refer to 0° only:

TABLE I
Hydration of Sugar at Weight-Molar Concentrations
(Morse)

Conc.	0°	10°	20°	30°	40°	50°	60°
0.1	53	43	45	3	6.9	8.8	11.5
0.9	5.5	5.8	5.8	5.4	5.0	4.4	3.3

(Berkeley)

0.1	14
0.9	5.3

Porter adds the following comments: "Both sets agree in giving diminishing hydration with increasing concentration. In other respects the agreement is not too close; but it must be remembered that in dilute solutions in particular the degree of hydration has an exceedingly small influence on the pressure.

¹ Trans. Faraday Soc., 13 Pt. I, 13 (1917).

"The values obtained for dilute solutions at low temperatures seem surprisingly large; but I am not aware of any argument which makes them impossible."

Most of these comments could be applied verbatim to many sols. Meanwhile (provided one agrees with Porter in ascribing the discrepancies in osmotic pressure to hydration at all) it is only necessary to put the question: how sorption experiments could conceivably lead to hydration numbers such as quoted, and to the variation with concentration and temperature, to realize the impossibility of this method of attack.

2. Everyone familiar with gelatin has come across brands which, when allowed to swell in cold water, will take up a weight of water equal to eight or ten times the original weight of dry gelatin. One gm of powdered gelatin placed in 8 or 10 gm of water will thus take up the whole of it and, at the best, leave a minute intergranular film. On warming, gelation occurs and, if the temperature is raised further, the viscosity of the sol decreases much more rapidly than that of water; the viscosity changes can be explained quite simply by decreased hydration, which, on the one hand, is exactly parallel with the behaviour of sugar in true solution, and on the other in complete agreement with what is known of the thermal changes during the swelling of gelatin gel. The viscosity of the gelatin-water system below solution temperature would be (conventionally) $= \infty$; with merely 5 per cent of the imbibed water released as a consequence of dehydration caused by warming the viscosity would be about 48 (water = 1), a perfectly probable value for an 11 or 9 per cent sol within one or two degrees of the gelation temperature.

While the water absorption during swelling thus leads to perfectly possible values for the volume of disperse phase, it is necessary to emphasize that in the case of gelatin, as in that of sugar, sorption experiments in saturated water would give no clue to the subsequent behaviour of the gel. A. G. Brotman¹ in the writer's laboratory carried out the following investigation: a quantity of gelatin leaf was allowed to swell in boiled, distilled water to saturation. The figures obtained were:

Weight of air-dry leaf	6.07 gm
Weight of saturated gel	79.5 gm
Gm of water per gm of gelatin	12.09

The saturated gel was warmed, the sol allowed to set and a portion of the gel thus obtained re-immersed in the same water, in which the first swelling had taken place; it was then allowed to swell a second time to saturation. The figures obtained were:

Weight of first "saturated" gel	31.6 gm
(Weight of dry gelatin in this 31.6 gm)	2.41 gm
Weight after 5 days' immersion	40.0 gm
Gm of water per gm of gelatin	16.5

It is obvious that sorption experiments could again give no indication of this behaviour. Quite similar results have been obtained by L. Arisz² in an

¹ J. Soc. Leather Trades' Chemists, 1921, 226.

² Kolloidchem. Beihefte, 7, 51 (1915).

exhaustive study of gelatin sols and gels; he draws the following conclusion: "This difference in behaviour must be traced back to the state of the gelatin in the gel, and it may be considered as a further proof that that state is not at every time completely determined by the ratio of water to gelatin."

3. Rubber provides a more interesting instance than even gelatin, partly because the viscosities produced by even small concentrations approach the high figures exhibited by nitro cotton sols, and partly because full data are available, which permit a comparison of the volume of disperse phase in a sol, i. e. the volume of solvent somehow attached to one gm of rubber, with the volumes taken up in swelling to equilibrium, both sets of figures being known for a number of solvents. E. Kirchof¹ has determined the viscosity of rubber sols in various solvents by a theoretically correct method: he used a capillary viscometer *at such pressures that the viscosity no longer varied with the pressure*. From these data he calculated the volumes of disperse phase by Hatschek's formula:

$$\varphi = \left(\frac{\eta' - \eta}{\eta} \right)^3$$

The relative viscosities (solvent = 1) and the percentage volumes of disperse phase (total volume = 100) calculated from them are given in Table II.

TABLE II

Solvent	Viscosity at the concentration of		Vol. of disperse phase at the concentr. of	
	0.5%	1.0%	0.5%	1.0%
Benzene	2.1	4.7	16.5	51.5
Carbon Tetrachloride	2.6	7.5	24.5	70.0
Tetrachlorethane	2.5	6.9	22.0	63.0

It will be noticed that the viscosities, and therefore the volumes of disperse phase, are throughout much higher in the Cl-substituted hydrocarbons than in benzene.

E. Posnjak² determined in Freundlich's laboratory the amounts of the

TABLE III

Pressure in gm per sq. cm.	Gm of liquid taken up by 1 gm of rubber			Cc of liquid taken up by 1 gm of rubber		
	C ₆ H ₆	CCl ₄	C ₂ H ₂ Cl ₄	C ₆ H ₆	CCl ₄	C ₂ H ₂ Cl ₄
720	5.139	—	—	5.85	—	—
1120	4.409	11.064	10.517	5.02	6.92	6.61
2120	3.278	8.466	6.785	3.73	5.29	4.26
3120	2.715	6.693	—	3.09	4.18	—
4120	—	5.885	—	—	3.63	—
5120	2.088	—	4.241	2.37	—	2.69

¹ Kolloid-Z., 15, 30 (1914).

² Kolloidchem. Beihefte, 3, 432 (1912).

same liquids taken up by rubber in swelling to equilibrium under considerable pressures. The details of the experimental arrangements need not be described here; it is merely necessary to mention that true equilibria were found. Posnjak's results are given in the first three columns of Table III; the volumes in the last three columns have been calculated from them. The pressures are pressures above atmosphere.

It will be noticed at once that *rubber swells more in the chlorine-substituted hydrocarbons than in benzene, i. e. it swells more in the solvents in which it exhibits higher viscosities*. Kirchof has compared the figures for "swelling" calculated from the viscosities by Hatschek's formula with those determined by Posnjak in the following Table IV, which shows not only qualitative, but quite remarkable quantitative agreement:

TABLE IV

	Ratio of quantities taken up in sol at concent. of		Ratio of quantities taken up in swelling (Posnjak) at pressures of			
	0.5%	1.0%	1120	2120	3120	5120 gm/sq. cm
$\text{CCl}_4/\text{C}_6\text{H}_6$	1.49	1.35	1.36	1.40	1.33	1.50
$\text{C}_2\text{H}_2\text{Cl}_4/\text{C}_6\text{H}_6$	1.33	1.22	1.12	1.15	—	1.12

These ratios, calculated on the one hand from the theoretical assumptions underlying Hatschek's formula, and on the other from actual determinations of swelling equilibria, are therefore seen to agree, excellently for the ratio carbon tetrachloride/benzene, and quite reasonably for tetrachlorethane/benzene; an agreement which it is impossible to regard as fortuitous.

Another point remains to be discussed. According to Posnjak one gm of rubber takes up 6.92 cc of carbon tetrachloride under a pressure of 1120 gm per sq. cm. From Table III it appears that in the 1% sol in this solvent the volume of disperse phase amounts to 70 per cent, i. e. one gm of rubber has taken up about 69 cc of solvent. This appears improbable at first sight, but if the course of the pressure-volume curves (Fig. 1) plotted from Posnjak's data is considered, the difficulty disappears, as the curves are markedly hyperbolic and the volumes imbibed rise steeply with decreasing pressure, so that at zero pressure they may assume very high values. It is not necessary either that the whole of the solvent bound by the disperse phase should be accounted for by the swelling of the micellae; these, like any other particles, are probably surrounded by a layer of less mobile liquid.¹

In conclusion it may be useful to examine briefly McBain's attitude to the fundamental problem of variable viscosity. He insists repeatedly, in speaking of nitro cotton sols, that "the apparent viscosity is not a true viscosity," "all actual measurements gave a distinct deviation from Poiseuille's law and thus do not show a true viscosity as defined by all physicists since 1860" etc. (Incidentally it is hardly correct to say that physicists have "defined" viscosity as involving an absolute constant. What they have done is to assume the viscosity coefficient independent of the shear gradient, and to develop on this basis expressions for various types of shear. Experimental demonstration of this constancy over a really extensive range is so far available for water only).

¹ Hatschek and Jane: Kolloid-Z., 40, 53 (1926).

It is not very clear what purpose this insistence on the apparent character of the viscosity is meant to serve. McBain cannot detect "yield values," in other words, the slightest pressure produces flow, as it does in normal liquids. The "apparent" viscosity which he determines in the capillary instrument certainly has the dimensions $ML^{-1}T^{-1}$, which are those of a true viscosity. The one conclusion which is both useful and inevitable when the variable character of the viscosity is emphasized, McBain, in common with many authors on the subject, does not draw: the conclusion that single viscosity measurements at arbitrary and unknown shear gradients are an inadequate

FIG. 1

foundation for theoretical deductions, especially on structure. If a physical "constant" varies with the conditions, it is obviously necessary to specify the conditions in which determinations were carried out. This position has been taken by the present writer since 1913, and in recent years has had the influential support of Freundlich.¹ If a real insight especially into structure is to be gained, complete viscosity-concentration-shear gradient surfaces must be determined, and such points as reproducibility of results, hysteresis, effect of short and prolonged shearing (which may be opposite²), onset of turbulence at anomalously low shear gradients, must all receive careful consideration. Finally, it would probably be sanguine to expect that the results of even so complete an investigation of any single sol, like that of nitro cotton, would be immediately "applicable throughout the whole field of colloids."

Summary

1. There is no direct evidence of the existence of ramifying aggregates in viscous sols, on the structure of which, however, the ultramicroscope in general gives little information.

¹ "Kapillarchemie," 2nd ed., pp. 742 et seq.; Freundlich, Neukircher and Zocher: *Kolloid-Z.*, **38**, 43, 48 (1926).

² Hatschek and Jane: *Kolloid-Z.*, **38**, 33 (1926). "The Viscosity of Ammonium Oleate Solutions."

2. There is direct ultramicroscopic evidence that high viscosity and even gelation may be exhibited by a sol without aggregation and without even mutual approach between the particles.
3. Sorption experiments cannot afford information regarding the degree of hydration in true or colloidal solution and its variation with concentration.
4. Consideration of the amounts of liquid taken up by gelatin or by india rubber during swelling shows that the volumes of disperse phase postulated by Hatschek's formula are not impossible or even improbable.
5. The behaviour of rubber in various solvents has been investigated. Solvents in which rubber swells more produce more viscous sols than those in which it swells less, in strict accordance with Hatschek's assumptions and in quantitative agreement with his formula.
6. If the viscosity of a given sol varies with the shear gradient, single measurements at arbitrary and unknown shear gradients have no theoretical value, least of all as a foundation for hypotheses regarding structure.

THE PARTIAL MOLAL VOLUMES OF WATER AND SALT IN SOLUTIONS OF THE ALKALI HALIDES*

BY VICTOR K. LAMER AND T. H. GRONWALL

In the course of a research on the extension of the Debye-Hückel theory of strong electrolytes to concentrated solutions, it was found necessary to establish empirical formulas in terms of the molality m for the partial molal volumes $\partial V/\partial n_o$ of water, and $\partial V/\partial n$ of salt, for the solutions of the alkali halides, the calculations being based on the density measurements of Baxter and Wallace.¹ The empirical formulas² are

$$\begin{aligned} \text{water: } \partial V/\partial n_o &= a_o + a_2 m^2 + a_3 m^3 + a_4 m^4, \\ \text{salt: } \partial V/\partial n &= b_o + b_1 m + b_2 m^2 + b_3 m^3, \end{aligned} \quad (1)$$

and Tables I and II give the coefficients in these formulas for the fifteen alkali halides, each at the temperatures 0° , 25° and 50.04° . The third column in the tables gives the value of m at the highest experimental point used in computing the coefficients, and extrapolation by means of the formulas beyond this value of m is not advisable.

Fig. 1 gives the graphs of the partial molal volume of the salt at 25° , computed from Table II. The formulas are derived as follows: Let V be the volume of the solution containing n_o mols of water and n mols of salt; then the molality m is given by

$$m = 55.5081 \, n/n_o, \quad (2)$$

and the volume y of solution containing one mol of water by

$$y = V/n_o \quad (3)$$

From (2) it follows that

$$\frac{\partial m}{\partial n_o} = -\frac{m}{n_o}; \quad \frac{\partial m}{\partial n} = \frac{55.5081}{n_o} \quad (4)$$

and from (3) and (4)

$$\begin{aligned} \frac{\partial V}{\partial n_o} &= \frac{\partial(n_o y)}{\partial n_o} = y + n_o \frac{dy}{dm} \frac{\partial m}{\partial n_o} = y - m \frac{dy}{dm}, \\ \frac{\partial V}{\partial n} &= \frac{\partial(n_o y)}{\partial n} = n_o \frac{dy}{dm} \frac{\partial m}{\partial n} = 55.5081 \frac{dy}{dm} \end{aligned} \quad (5)$$

Now m and y may be computed directly from the volume V of solution and weights of water and salt measured by Baxter and Wallace. A curve of the fourth degree

$$y = A_o + A_1 m + A_2 m^2 + A_3 m^3 + A_4 m^4 \quad (6)$$

*Contribution from the Chemical Laboratories of Columbia University, No. 527.

is then fitted to the computed points. Doing this by the method of least squares, besides being extremely laborious, would be of doubtful value, since the number of experimental points is small. The curve was therefore simply passed through the five experimental points corresponding to $m = 0$ (the value of y being computed from the volume of 1 g. of water,¹ and the lowest and the three highest m -values of Baxter and Wallace. This curve fits the intermediate points very well, as is seen from Table III, where the second column contains the experimental y -values and the third the difference between this and the y computed from equation (6):

FIG. 1

1 = CsI; 2 = RbI; 3 = CsBr; 4 = KI; 5 = CsCl; 6 = RbBr; 7 = NaI; 8 = KBr; 9 = LiI; 9a = RbCl; 10 = KCl; 11 = NaBr; 12 = LiBr; 13 = NaCl; 14 = LiCl

In one case only (KCl at 0°), the differences are slightly greater than these; in all other cases they are considerably smaller. Let m_i, y_i ($i = 0, 1, 2, 3, 4$) be five points, $f(m) = (m - m_0)(m - m_1) \dots (m - m_4)$ and $f_i(m) = f(m)/(m - m_i)$; then the fourth degree curve passing through the five points is given by Lagrange's interpolation formula

$$y = \sum_{i=0}^4 y_i \frac{f_i(m)}{f_i(m_i)} \quad (7)$$

¹ Landolt and Börnstein: Physikalisch-Chemische Tabellen, p. 43 (1912).

and the coefficients A_0, \dots, A_4 are found by multiplying out the products and collecting terms.¹ The coefficients in (1) are then found at once by substituting (6) in (5). To form an estimate of the error in $\partial V/\partial n$, for instance, due to errors $\Delta y_1, \dots, \Delta y_4$ in the experimental values of y_1, \dots, y_4 we observe that the error in y is, according to (7)

FIG. 2

Relative effect of an error in the experimental values of y (the volume of solution containing one mol of water) at $m = 0.2, 1.5, 2.5$, and 4.0 , respectively, which correspond approximately to the points used in constructing Table III, upon the calculated value of $\partial V/\partial n$ at various molalities.

TABLE III

KCl at 25°

m	y exp.	y exp. $-y$ calc.
0.0000	18.0683	0.0000
0.1668	18.1505	0.0000
0.2742	18.2052	+0.0008
0.3383	18.2381	+0.0011
0.6839	18.4188	+0.0024

2.4694	19.4045	0.0000
3.7470	20.1454	0.0000

¹ The actual computation was done by the "divided difference formula," which is easier to handle numerically; see Whittaker and Robinson: "Calculus of Observations," (1924).

$$\Delta y = \sum_{i=1}^4 \Delta y_i \frac{f_i(m)}{f_i(m_i)}$$

and consequently, by (5)

$$\Delta \left(\frac{\partial V}{\partial n} \right) = \sum_{i=1}^4 \Delta y_i \cdot 55.5081 \frac{f'_i(m)}{f_i(m_i)} \quad (8)$$

In Fig. 2, the coefficients of $\Delta y_1, \dots, \Delta y_4$ in (8) are plotted against m and marked 1, 2, 3, 4; they were calculated for $m_0 = 0$, $m_1 = 0.2$, $m_2 = 1.5$, $m_3 = 2.5$, $m_4 = 4.0$ which correspond roughly to the five points used in constructing Table III. Fig. 2 shows, for instance, that at $m = 0$ as well as at $m = 4$, an error in y , contributes an error in $\partial V/\partial n$ 366 times as large.

If the experimental error in y_1 does not exceed a unit in the sixth significant figure, then the error due to it in $\partial V/\partial n_0$ should not exceed four units in the fourth significant figure. Similar estimates may be made of the errors due to errors in y_2, y_3 and y_4 , and the corresponding errors in $\partial V/\partial n_0$ and $\partial V/\partial n$, with the result that the maximum error to be expected in using Tables I and II is two units in the fifth significant figure of $\partial V/\partial n_0$, and five units in the fourth significant figure of $\partial V/\partial n$, i. e., ± 0.05 cc. In some of the determinations of the volume of the solutions, the error may be at least five parts per million, so that a probable error of 0.20 cc. in $\partial V/\partial n$ is possible.

A check upon the accuracy of the results for practical purposes can be obtained by considering the differences between the values of the partial molal volumes of the salt $\partial V/\partial n = \bar{V}$ at infinite dilution.

Since at infinite dilution the partial molal volume of a given anion should be independent of the cation with which it is associated, the difference

$$\bar{V}_{MCl} - \bar{V}_{MBr}$$

should be a constant at a given temperature and should represent the difference

$$\bar{V}_{Cl^-} - \bar{V}_{Br^-}$$

Likewise the difference $\bar{V}_{NaX} - \bar{V}_{LiX}$ should be constant and represent the difference in partial molal volumes of the sodium and lithium ions at infinite dilution.

Some of the possible combinations are assembled in Table IV. They were obtained by direct combination of the respective values of b_0 in Table II.

A consideration of the data of Table IV shows that with the exception of those differences which involve KCl at 0°, 25° and 50°C. and also CsI and RbCl at 0°C. that the values for a given combination check very well, usually within one or two tenths of a cc. The values for b_0 in Table III are therefore on the whole correct to within this range of variation.

Lamb and Lee¹ measured by a very ingenious and accurate method the densities of highly dilute solutions of sodium and potassium chlorides. Their data yield 10.386 at 20° C. for the difference for the partial molal volume of potassium ion minus sodium ion at infinite dilution, while our calculations for the same difference using the bromides and iodides yield respectively 10.36 and 10.35 at 25° C. The difference K—Na obtained from the respective chlorides is 9.80 or 0.55 cc. lower. As was noted above the KCl density data do not fit the empirical equation (6) as well as the other data, and after rechecking our figures we are obliged to attribute the discrepancy to an error which has crept into the density data for KCl. Since Baxter and Wallace employed the same weighed portion of KCl for many of their density determinations at the different temperatures it is possible that the source of the error may reside entirely in a single weighing.²

We may avoid this uncertainty and obtain a value for \bar{V}_{KCl} at infinite dilution in the following way: If we grant that \bar{V}_{NaCl} is correctly determined in Table II and that the difference $\bar{V}_{K^+} - \bar{V}_{Na^+}$ as given by the bromide and iodide data in Table IV is correct as seems quite certain from the check with Lamb and Lee's data, then the partial molal volume of KCl at infinite dilution should be $13.44 + 11.00 = 24.44$ at 0° instead of 22.92 as indicated by the b_0 value in Table II; similarly for 25° C. we find $17.22 + 10.35 = 27.57$ instead of 27.02 and for 50° C. 28.27.

These calculated values may be checked in the same manner by employing the differences between the lithium and potassium series, and assuming that the b_0 value for lithium chloride is correct. Table V lends further weight to the assumption that the data for KCl are incorrect.

¹ J. Am. Chem. Soc., **35**, 1683 (1913).

² The coefficients b_1 and b_2 in Table II also indicate irregularities in the data for KCl, RbCl (0°) and CsI (0°). The same holds true of course for the data in Table I. Using a 3rd degree equation on the first and highest two experimental points we get 27.13 cc. as the value for KCl at 25° C. A third degree equation on the first three experimental points yields 27.15 cc. The error evidently resides in the first experimental point; namely 0.1688m of Table III.

TABLE V
 $\bar{V}_{KX} - \bar{V}_{LiX}$

Anion employed	0.00°	25.00°	50.04°
Cl	(6.89)	(9.43)	(10.61)
Br	8.41	9.99	11.10
I	8.44	10.08	11.21
Average	8.42 ₅	10.04 ₅	11.15 ₅

The results based upon the correctness of the b_0 for LiCl in Table II and the averaged values of Table V yield for \bar{V}_{KCl} at infinite dilution the values 24.45₅ (0°); 27.53₅ (25°) and 28.62 (50°), which are in substantial agreement with those based upon the NaCl data.

In view of this concordance we feel that the most probable values for \bar{V}_{KCl} are 24.45 (0°); 27.55 (25°) and 27.32 (50.04°) instead of the b_0 values of Table II.

Adjusted values for \bar{V}_{RbCl} at 0° C. based upon the results of Table VI yields 28.86 (NaCl series) and 28.88 (LiCl series) or 28.87 as the most probable value for RbCl instead of the b_0 value 29.92 in Table II.

TABLE VI		
X	$\bar{V}_{RbX} - \bar{V}_{NaX}$	$\bar{V}_{RbX} - \bar{V}_{LiX}$
Cl	(16.48)	(13.89)
Br	15.44	12.80
I	15.40	12.90
Average	15.42	12.85

From the bromide-iodide combination Table IV and the b_0 value for CsBr we get \bar{V}_{CsI} at 0° = 53.18. From the iodide-chloride combination for lithium and sodium (K, Rb and Cs cannot be used in this series) we get, using the b_0 value for CsCl, \bar{V}_{CsI} at 0° = 53.43.

The value 53.18 is based upon four differences and the weighted average for \bar{V}_{CsI} at 0° becomes 53.26 instead of 53.77 as given in Table II.

Unfortunately the principle upon which the adjustments are based is valid only for infinite dilution, and we cannot estimate in advance how the higher coefficients in Tables I and II, which give a measure of specific effects between the ions should be adjusted.

Discussion of Results

The interpretation of partial molal volumes in aqueous solution is unquestionably a matter of considerable complexity, and any attempt to "explain" the values on simple assumptions must necessarily encounter difficulties. Since the values of \bar{V} are almost always smaller than the corresponding molecular volumes of the solid salts, and in certain cases notably Na_2CO_3 and $MgSO_4$ even negative in value, it is necessary to assume the operation of at least two opposing factors; viz:

- (a) The true volume of the ions;
 (b) the compression of the solvent about the ion usually denoted as electrostriction.¹

As its name indicates (b) is considered to be brought about by the attraction of the water dipoles through the electric field created by the ions, with the result that an increased density and orientation of the water molecules occurs in the immediate neighborhood of the ions.

FIG. 3

Effect of temperature on the partial molal volumes of NaCl and of LiCl at infinite dilution.

- NaCl—present investigation
 △ NaCl—Lamb and Lee (20°C)
 + NaCl—Wade (18°C)—calculated by Lewis and Randall: "Thermodynamics," p. 36.
 □ LiCl—present investigation
 × LiCl—Lamb and Lee (20°C).

Since the data of this paper were assembled, T. J. Webb² has published a very interesting mathematical theory of electrostriction along the lines just sketched. He has also calculated the free energies of hydration of the alkali halides (except lithium) by considering their ions to behave as charged spheres, and compares the radii so obtained with those calculated from the data on partial molal volumes at great dilution. He obtains very plausible values for the radii and in the limited cases where the necessary data are available agreement appears to be secured between the two methods. He did not discuss the effect of temperature and it will be important to see whether the radii which he has calculated can account for the variation in partial molal volume with temperature. As Table IV shows the temperature coefficient is usually positive for the differences as written, one of the most marked temperature coefficients being given by the difference $\bar{V}_{Li^+} - V_{Na^+}$. In Fig. 3 we have plotted the limiting values of \bar{V} for LiCl and NaCl against the temperature. Calculations³ which we have made for the "apparent" diameter of the ions "a" in the Debye-Hückel theory of electrolytes indicate that this quantity

¹ Drude and Nernst: *Z. physik. Chem.*, **15**, 79 (1894).

² T. J. Webb: *J. Am. Chem. Soc.*, **48**, 2589 (1926).

³ Forthcoming publication. For a preliminary abstract see *Science*, **64**, 121 (July 30, 1926).

changes markedly with temperature, and it is possible that the so-called radii of the ions calculated by Webb may also prove to vary with the temperature, but according to his picture of ionic size it would be difficult to interpret such a variation. That arbitrary values for the ionic radii will not in themselves explain the values for all of the alkali halides is evident when we consider the lithium salts. The radius for lithium is generally given as smaller than that of sodium and consequently the electric field strength about the lithium ion should be greater with the result that a smaller value of \bar{V} would be expected. As Table II and Fig. 1 show the reverse is the case at temperatures below 50° C., NaCl having a lower value at high dilution than does LiCl, and the same is true of the bromides and iodides. The curves cross above 0.5M and the expected regularity is obtained only in concentrated solution.

FIG. 4

1 = LiI; 2 = CsI; 3 = CsBr; 4 = LiBr; 5 = CsCl; 6 = LiCl; 7 = NaI; 8 = KI; 9 = KBr and RbI; 10 = NaBr; 11 = NaCl; 12 = RbBr; 13 = RbCl and KCl.

Lamb and Lee's results at 20° C. for infinite dilution which we give below yield the same result; namely, LiCl = 17.125; NaCl = 15.714; KCl = 26.10; NH₄Cl = 24.95. Wade's data¹ gives HCl = 17.82 at 18° C, which is even more difficult to interpret. We suggest that as the ionic size decreases factors other than the field strength at the surface of the ion become important. Thus in the extreme case of a proton (hydrogen ion) there is not sufficient surface for more than one molecule of H₂O to be compressed about it with the result that the proton is absorbed by the water molecule and the charge is distributed upon the hydronium ion H₃O⁺. Lithium ion very likely behaves in a similar way, i. e., it forms a true chemical hydrate. There is much

¹ Wade: Landolt-Börnstein "Tabellen," p. 287 (1912).

evidence that the hydrogen ion exists only in this mono-hydrated form. If this is the case then we should employ the partial molal volume of hydronium chloride $[\text{H}_3\text{O}]^+ \text{Cl}^-$ which at infinite dilution equals the sum of the values for HCl and for H_2O ; namely 35.87 cc. It is interesting that this value is not very different from that of the corresponding ammonium chloride; namely 34.95 cc.

It is well known that the general behavior of NH_4^+ as an alkali ion does not accord with its atomic or radical weight, which places it between lithium and sodium. Instead it resembles K^+ and Rb^+ much more closely in properties such as the solubility of the chlorplatinate and bitartrate. According to the modern physical view these properties are governed in the case of the larger ions primarily by the size of the sphere upon which the charge of the ion is distributed, and the partial molal volume of NH_4Cl which is practically identical with that of RbCl lends support to this view.

The difference between the partial molal volume and the molecular volume of the solid salt; namely $(\bar{V} - V)$ gives the change in volume which one mol of salt produces on dissolving, the composition of the solution remaining unchanged. Fig. 4 gives a plot of the values of $(\bar{V} - V)$ in terms of the molality of the solution. These values differ somewhat from the values given by Baxter and Wallace, except at infinite dilution, since their calculations give what is essentially the integral change in volume; i. e., the volume change which the salt and pure water undergo in forming a solution of a given molality. The data of Fig. 4 were calculated from the empirical expressions of Table II and in certain cases may carry the errors previously referred to.

Most striking are the values of the cesium salts and particularly the iodide which actually expands on dissolving. Baxter and Wallace have discussed this question from the standpoint of T. W. Richards' theory of the compressible atom and point out that the atoms are undoubtedly highly compressed in the solid state. Webb's calculations also indicate this since they show that the radii of the ions in solution are on the average about 0.47 Å larger than the corresponding values obtained from X-ray measurements on crystals. In regard to the position of the cesium salts in Fig. 4, it is well to point out that the atoms (ions) of these salts are arranged in the crystal in the form of a body-centered lattice, while in the case of all of the other alkali salts the arrangement is of the simple cubic or NaCl type.

Summary

1. A rapid analytical method for the calculation of the partial molal volumes of the salt and of the solvent from density determinations is described.

2. Values for the partial molal volumes of the water and of the salt at 0°, 25°, and 50° C. have been calculated for the fifteen alkali chlorides, bromides and iodides by the use of a fourth degree equation to represent the density data of Baxter and Wallace. The effect on the final result of errors in the original data are discussed.

3. There are strong indications that the density data for KCl at 0°, 25° and 50° C. and for RbCl and CsI at 0° C. may be sufficiently in error to ac-

count for certain irregular results. The values for the other salts are consistent with one another. On the basis of this consistency and the principle of the additivity of the properties at infinite dilution adjustment in the limiting values for KCl, RbCl and CsI has been made.

4. The bearing of the results and particularly the effect of temperature have been briefly discussed in the light of T. J. Webb's theory. The position of NH_4^+ ion in the alkali series is interpreted on the basis of its partial molal volume.

DIFFUSION OF AQUEOUS SODIUM SILICATE SOLUTIONS ACROSS SEMIPERMEABLE MEMBRANES

BY PHANI BHUSAN GANGULY

From the measurements of scattering, a very marked change has been observed as the molar ratio of $\text{SiO}_2 : \text{Na}_2\text{O}$ increased beyond 3 : 1. In the following experiments the distribution of the silicate solutions across different membranes has been investigated in the hope that more precise information as to the change in colloidal aggregates with increase of ratio, will be available. Solutions of the silicates were allowed to attain equilibrium against water. Both parchment and collodion membranes have been used. After equilibrium the respective solutions have been analysed, their osmotic pressures measured, and also their pH values ascertained. From these measurements an attempt has been made to determine the colloidal aggregations of sodium silicates, and to follow the change in the colloidal properties with change of ratio.

A parchment membrane was clamped in position in a Donnan membrane vessel. A solution of sodium silicate of known concentration was put in one compartment of the vessel, the other compartment containing distilled water. The volume of the water used was adjusted in such a way that after equilibrium, the volumes of liquid in both the compartments were about the same. To hasten the equilibrium the solutions were stirred by a current of nitrogen. The nitrogen was carefully purified from carbon dioxide, washed and dried. Before entering the membrane vessel, it passed through the bubblers A and A_1 , and B and B_1 . The bubblers A and A_1 , contained the same silicate solutions as in the membrane vessels, whilst B and B_1 , acted only as traps. Atmospheric carbon dioxide was excluded by another trap at C and C_1 , attached to the exit tubes. The arrangement is shown diagrammatically in Fig. 1. A series of such vessels were set up so that they could all be stirred simultaneously. To determine the equilibrium point, solutions were drawn out from time to time and analysed. It was found that the solutions attained equilibrium in about one week's time, as was determined by the constancy of analytical results.

When collodion was used as the membrane, the membrane vessel took the form of two concentric tubes. Water was put in the outer vessel whilst the inner tube contained the silicate solutions. The volumes of liquids used were again adjusted so far as possible, so as to get the same volume of solution in both the tubes after equilibrium. The inner tube consisted of a collodion sack, which was mounted on to a glass tube. For the preparation of the collodion sack the commercial "Necol", which is a 13% solution of collodion, was used. The sack was made from the inside of a tube of the required size, care being taken to avoid the formation of air bubbles. It was found that better results could be obtained by holding this tube symmetrically inside an

outer jacket with the help of bored corks, and thereby excluding the warmth of the hand. A current of air was also drawn through the tubes to hasten the drying of the collodion. The sack was then put on to a piece of glass tube of size just big enough to allow the sack to slip on easily. In about a couple of hours the collodion sack dries a little and thus grips the tube very firmly, making a perfectly air-tight joint. To avoid the shrinking of the rest of the sack while it is drying to grip the tube, it was kept full of water. This was found to be a more satisfactory process than the usual practice of tying the sack with rubber bands or threads.

FIG. 1

No stirring was done in these cases, but sufficient time was allowed for the attainment of equilibrium, which was determined as before, by the concurrence of analytical results. After equilibrium the solutions were drawn out, their total volume and density measured, and also analysed. The silica was estimated by repeated evaporation to dryness with hydrochloric acid, and the sodium was estimated in the filtrate as sodium chloride. The experimental analytical results are given in Tables I-II.

From these tables we find that sodium silicate solutions contain considerable proportions of non-diffusible ions or combined molecules. The difference in the analytical values of SiO_2 and Na_2O for the solution H, in which the molar ratio of silica to alkali is 2:1, is however, quite small, showing thereby that this solution contains a correspondingly small amount of non-diffusible matter. If this solution consisted of simple ions like Na^+ and SiO_3^- , and the non-diffusible matter consisted of combined ions of the general type $[\text{SiO}_3]_n^-$, then, according to the Donnan membrane law, there should be an increase of

E.	3.0	0.7736	0.2640	0.7332	0.2524	.0404	0.0116
G.	2.5	0.7722	0.3178	0.7338	0.3022	.0384	0.0156
H.	2.0	0.7568	0.3852	0.7496	0.3896	.0072	-0.0044

silica in the silicate compartment, which should be counterbalanced by an increase of sodium in the water compartment satisfying the relation:—

$$[\text{Na}]_{\text{sil}} \times [\text{SiO}_3]_{\text{sil}} = [\text{Na}]_{\text{water}} \times [\text{SiO}_3]_{\text{water}}$$

In the case of solution H, we find a slight increase of silica in the silicate compartment and an increase of sodium on the other side of the membrane, which is so far in accordance with the membrane law. Substituting the actual values obtained with parchment membrane, in the above equation we get,

$$[\text{SiO}_3]_{\text{sil}} = \frac{[\text{Na}]_{\text{water}} \times [\text{SiO}_3]_{\text{water}}}{[\text{Na}]_{\text{sil}}} = \frac{.7748 \times 1.4918}{.766 \times 60.3} = 0.02502.$$

The value experimentally found gives

$$[\text{SiO}_3]_{\text{sil}} = 0.02499.$$

which is slightly less than the value calculated above. The experimental analytical concentration of silica in the silicate chamber on the contrary should have been slightly higher than the above calculated value because the analytical value represents the sum total of both the non-diffusible silica as well as the ionic silica. Assuming then that the ions in the 2:1 ratio silicate solution are Na⁺ and SiO₃⁻ the above divergence leads one to infer that the non-diffusible aggregate is not only [(SiO₃)_n]⁻, but consists also of a more complex combination probably containing both sodium and silica.

As the ratio of silica to alkali in the original silicates increases, the distribution across the membranes become more complicated. There is always a larger amount of SiO_2 in the silicate compartment after equilibrium, but there is also a greater amount of sodium in the same compartment. The excess of silica in the silicate compartment, is however proportionately much greater than the excess of sodium in the silicate compartment over the sodium in the water compartment.

FIG. 2

In the last column of Table III the excess of silica present in the silicate compartments over and above the amounts corresponding to the excess of sodium present, is given.

This amount shows a marked increase at the ratio 3.3. This is clearly seen from Fig. 2, in which the last column of Table III is plotted against the molar ratio of the original silicates. Thus it is evident that the amount of indiffusible silica, whether in the form of complex ions or combined molecules increases at a much enhanced rate after the ratio 3. This result is quite in agreement with the previous observations based on scattering and ultra-microscopic measurements.

The variations of the amounts of non-diffusible matter with change of ratio, are shown more clearly in Tables IV, V.

TABLE III

	Molar ratio	Increase in the silicate compartments		SiO_2 corresponding to Na_2O in the previous column	Difference SiO_2
		SiO_2	Na_2O		
A.	4.2	0.7860	0.0640	0.2612	0.5248
B.	3.95	0.6116	0.0590	0.2240	0.3876
C.	3.8	0.4054	0.0502	0.1855	0.2199
D.	3.3	0.2644	0.0254	0.0815	0.1828
E.	3.0	0.0520	0.0134	0.0391	0.0129
G.	2.5	0.0620	0.0086	0.02334	0.03866

When the equilibrium molar ratios of the two compartments, are plotted against each other, a curve (Fig. 3) is obtained, which shows clearly that the increase in molar ratio in the silicate compartment is far greater than the change in the molar ratio in the water compartment.

A.	4.2	5.532	2.512	2.797	1.27
B.	3.95	4.960	2.7105	2.274	1.242
C.	3.8	4.257	3.238	1.610	1.224
D.	3.3	3.580	2.974	1.3960	1.160
E.	3.0	3.013	2.986	1.055	1.050
G.	2.5	2.5014	2.493	1.054	1.050
H.	2.0	2.020	1.978	1.009	0.980

When the values in the various columns of the above tables are plotted, curves are obtained, which all show the characteristic change between the points corresponding to 3.0 and 3.3 ratios in the original silicate solutions. The general nature of the curves obtained with both parchment and collodion membranes, is the same. Both sets of curves show practically the same change after the ratio 3.0. In the case of the collodion membrane however there is a greater separation, inasmuch as, the excess of silica concentration in the silicate compartment is proportionately greater than that in the case of the parchment membrane. A possible reason for this might be that the parchment allows certain ions or ionic complexes to pass through, which however are not able to diffuse across the collodion membrane.

The simultaneous presence of an excess of both SiO_2 and Na_2O , in the silicate compartments, shows that a part of the non-diffusible portion must consist of both sodium and silica. There are probably two kinds of non-diffusible matter present in the silicates,

(1). Complex silicate ions like $[(\text{SiO}_3)_n]^-$

(2). Complex molecules containing both silica and sodium, which may be represented as

The equilibrium state of such a system would thus be as follows,

Silicate compartment	Water compartment
Na^+	Na^+
$(\text{SiO}_3)^-$	$(\text{SiO}_3)^-$
$[(\text{SiO}_3)_n]^-$	Na^+
$[(\text{Na})_x (\text{SiO}_n)_y]_p^-$	Na^+

FIG. 3

The molar complex $[(\text{Na})_x (\text{SiO}_n)_y]_p$, if present in sufficiently large quantity will give at equilibrium a greater analytical value for both SiO_2 and Na_2O in the silicate compartment.

From an examination of Fig. 4, in which the ratio of the sodium contents of silicate and water compartments respectively, have been plotted against the molar ratio of the silicate solutions, it is evident that the sodium silica molecular complexes present in the silicates, increase with increase of molar ratio of the original silicate solutions. This curve also exhibits the characteristic bend after the ratio 3.0, though not so marked as in the other cases.

After the silicate solutions attained equilibrium, they were also used for a series of osmotic pressure measurements. The osmotic pressure of the liquid in the silicate compartment was measured against the liquid in the water compartment. The type of osmometer used is shown in Fig. 5. The results obtained are shown in Table VI.

TABLE VI

Parchment membrane solutions

	Molar ratio	Observed osmotic pressures in mm of Hg.	C. where, $C = \frac{M \times p \times T_0}{22.4 \times 760 \times T_1}$
A.	4.2	1.91	$10.28 \cdot M \times 10^{-5}$
B.	3.95	1.45	$7.8 \cdot M \times 10^{-5}$
D.	3.3	0.52	$2.75 \cdot M \times 10^{-5}$
E.	3.0	0.31	$1.67 \cdot M \times 10^{-5}$
G.	2.5	0.29	$1.55 \cdot M \times 10^{-5}$
H.	2.0	0.23	$1.23 \cdot M \times 10^{-5}$

In the last column of Table VI, the percentage of colloidal matter present has been calculated in terms of M , the answer molecular weight of the colloidal material, by using the equation,

$$C = \frac{M p T_0}{22.4 \times 760 \times T_1},$$

where p is the observed osmotic pressure in mm of Hg, and C is the percentage of colloid.

In Table VI we find that the value of C rises in a very marked way with the rise of ratio of the silicates. By plotting C , the colloid concentration against molar ratios, a curve, Fig. 6, is obtained which shows the same rapid rise after the ratio 3.0.

FIG. 5

It is not possible to get any actual measurements of the total colloidal matter present, as nothing is known about M , the average molecular weight of the colloid. So far as these experiments go, they support the general conclusions already arrived at about the constitution of the silicates in relation to increasing ratios of SiO_2 to Na_2O .

Hydrolysis does not seem to play any important role during these distribution processes across membranes. To ascertain this point a few pH measurements of the solutions after equilibrium were done. The pH measurements were done potentiometrically, a hydrogen electrode vessel of the Walpole type being used. A saturated solution of potassium chloride was used as the liquid junction. Some of the results obtained are given in Table VII.

TABLE VII
Hydrolyses in sodium silicate solutions

Solution	Molar ratio	Observed E. M. F. Silicate compartment (volts)	Water compartment (volts)	pH Silicate compartment	pH Water compartment
A.	4.2	0.8930	0.8896	10.88	10.83
C.	3.8	0.8892	0.8862	10.80	10.765
G.	2.5	0.8980	0.8964	10.964	10.937

FIG. 6

Considering therefore that $[H] \times [OH] = K_w$, the dissociation constant of water, from the above pH values we find that the solutions in both the compartments, are practically equally hydrolysed. This conclusion is borne out by the experiments of Harman (private communication) who also found that in the higher ratios the silicates were considerably less hydrolysed.

Summary

1. The diffusion across membranes of aqueous sodium silicate solutions, using both parchment and collodion membranes, has been investigated.
2. After equilibrium the solutions have been analysed, and it was found that the silica concentration in the original silicate compartment, was generally greater than the silica concentration in the other compartment.
3. The distribution was greatly dependent on the original molar ratios of the solutions. Solutions up to the molar ratio 3.0, showed very little variations in concentrations during diffusion, showing thereby that the quantity of non-diffusible matter in those solutions, was comparatively small.

4. The quantity of non-diffusible matters increased very rapidly after the ratio 3.0. This result is quite in line with the previous measurements on the light-scattering of the silicate solutions, and shows beyond doubt that after the ratio 3.0, the quantities of colloidal matters in the silicate solutions increase at a very rapid rate.

5. There was generally more silica left in the silicate compartments, but the amount of sodium in the silicate compartments, was also found to be greater than the amount of sodium in the water compartment. This is interpreted to indicate that the colloidal matters present in the higher ratio silicate solutions, are in the form of molecular aggregates or ionic complexes containing both sodium and silica. It is suggested that the equilibrium state is as follows:

Silicate compartment	Water compartment
Na^+	Na^+
$(\text{SiO}_3)^-$	SiO_3^-
$[(\text{SiO}_3)_n]$	Na^+
$[(\text{Na})_x (\text{SiO}_n)_y]_p$	Na^+

6. A series of osmotic pressure measurements of the solutions after equilibrium, showed that the quantity of colloidal matters in the silicates increased with ratio.

7. Measurements of pH of the solutions after equilibrium showed that hydrolysis does not take any prominent part during these distribution processes.

In conclusion the author wishes to express his thanks to Prof. F. G. Donnan, for his many valuable suggestions and for his kind interest in this work.

THE METHANE EQUILIBRIUM IV

BY R. C. CANTELO

The data given in the third paper¹ of this series permits the calculation of the free energy decrease attending the synthesis of methane from amorphous carbon and hydrogen.

The free energy expression for the Second Law of Thermodynamics is given by

$$d \left(\frac{-\Delta F}{T} \right) = \frac{\Delta H}{T^2} \cdot dT \text{ and } \Delta H,$$

the increase in heat content may be expressed in terms of the heat capacities of the substances involved.

If ΔC represents the difference in the heat capacities of the products and the reactants, the equation becomes

$$-\frac{\Delta F}{T} = \int \frac{\int \Delta c \cdot dT + \Delta H_0}{T^2} \cdot dT + I$$

where ΔH_0 and I are constants of integration.

ΔH_0 may be calculated from the fact that for the reaction

If ΔC be expressed in series form,

$$\Delta C = \Delta C_0 + \alpha T + \beta T^2 + \dots$$

and the free energy expression simplifies to

$$\frac{-\Delta F}{T} = \frac{-\Delta H^0}{T} + \Delta C_0 \ln T + \frac{\alpha}{2} T + \frac{\beta}{6} T^2 + I$$

or
$$-\Delta F = -\Delta H_0 + \Delta C_0 \cdot T \ln T + \frac{\alpha}{2} T^2 + \frac{\beta}{6} T^3 + I T$$

Dixon, Campbell, and Parker² determined the (C_p^T/T) curve for methane and gave the linear equation

$$C_p^T = 3.47 + 0.019 T$$

to represent their results. This equation is used in the calculations given below.

For hydrogen³

$$C_p^{O,T} = 6.52 + 0.00044 T.$$

For carbon⁴

$$C_p^{O,T} = 1.1 + 0.0024 T + 4.0 \cdot 10^{-7} T^2$$

This latter equation gives the value 2.4 for the atomic heat of carbon at ordinary temperatures. The atomic heat of amorphous carbon at ordinary temperatures is 2.6

¹ J. Phys. Chem., 31, 246 (1927)

² Proc. Roy. Soc., 100A, 1 (1921).

³ Saunders: J. Phys. Chem., 28, 1151 (1924).

⁴ Lewis and Randall: "Thermodynamics and Free Energy," 569 (1923).

These values give

$$\begin{aligned}\Delta C_0 &= -10.67 \\ \alpha &= +0.01572 \\ \beta &= +4.0 \cdot 10^{-7}\end{aligned}$$

The free energy equation thus becomes

$$-\Delta F = 19,280 - 10.67 T \ln T + 0.000786 T^2 + 0.6 \cdot 10^{-7} T^3 + I T.$$

The value of I , the constant of integration, may be determined from the values of $-\Delta F$ calculated from the determined equilibrium constants. For this calculation, the values obtained by the writer with ethylene as the initial system were used. This gave an average value of 42.2. The "constant" varied between +41.3 and +43.3.

$$-\Delta F = 19,280 - 10.67 T \ln T + 0.0786 T^2 + 0.00000006 T^3 + 42.2 T$$

which gives for $T = 298$ that

$$-\Delta F_{298} = 14,500 \text{ calories for the reaction } C (\text{amorph}) + 2H_2 \rightleftharpoons CH_4.$$

Lewis and Randall¹ have calculated $-\Delta F_{298}$ for the reaction

$$C (\text{graph}) + 2H_2 \rightleftharpoons CH_4; -\Delta F_{298} = 12,800 \text{ calories and } C (\text{amorph}) + 2H_2 \rightleftharpoons CH_4; -\Delta F_{298} = 14,500 \text{ calories from which for the reaction}$$

$$C (\text{amorph}) \longrightarrow C (\text{graph}); -\Delta F_{298} = 1,700 \text{ calories.}$$

Summary

The free energy decrease attending the synthesis of methane from amorphous carbon and hydrogen has been calculated and found to equal 14,500 calories.

ADSORPTION BY METALLIC HYDROXIDES. I ADSORPTION OF ARSENIOS ACID BY PRECIPITATED FERRIC HYDROXIDE

BY KSHITISH CHANDRA SEN

General Introduction

The study of adsorption of various substances by means of hydrated oxides as adsorbents has been done mainly from two points of view, namely (1) to compare their adsorptive power with adsorbents such as animal charcoal, etc, and (2) whether any relation between the coagulating power and adsorption of ions exists or not. In the first case, mainly the adsorption of dyes and in some cases that of acids and salts has been examined whereas in the second case both salts and acids were used with a colloidal solution of the hydroxide. As an instance of the first case, a paper by Freundlich and Poser,¹ in which a comparative study of the adsorptive power of alumina, bole and animal charcoal on some basic and acid dyes, and of salts of the alkaloids and certain other organic bases was made, may be mentioned. The papers by Gann,² Ishizaka,³ and those by Weiser and his collaborators,⁴ are examples of the second type. There is another investigation which has drawn the attention of several investigators, namely the adsorption of arsenious acid by hydrated ferric oxide. Besides these—though stray cases of adsorption by hydrated iron, aluminium and chromium oxides appear in the literature, it seems that no systematic attempt has been made to make a comparative study of the adsorptive power of these hydroxides for inorganic and organic acids.

In a previous paper,⁵ I have shown that when a ferric chloride solution is mixed with sufficient quantity of arsenious acid, and then caustic alkali is added, no precipitation of the ferric hydroxide occurs, but instead a colloidal solution of negatively charged ferric hydroxide is obtained. In a later paper,⁶ the same behaviour with chromium hydroxide was also shown. These results indicated that the stabilisation of the hydroxides may be due to the adsorption of the negatively charged arsenite ions, and hence about two years ago an investigation on the adsorptive power of these hydroxides for arsenious acid was started. The results obtained were of sufficient interest to extend the investigation to other acids, mainly organic, the experiments being done with all the three oxides under varying conditions. The object of this series of papers is to present the results obtained, and their possible application to the theoretical problems of adsorption and colloid coagulation has been pointed out.

Adsorption of Arsenious Acid by Ferric Hydroxide

The adsorption of arsenious acid by ferric hydroxide has been studied by several authors. The investigation was started by Bunsen and Berthold,¹ who observed the great adsorption power of ferric hydroxide for arsenious acid and considered the combination to be a basic ferric arsenite. Seventy years after the publication of this result, the subject was quantitatively investigated by Biltz² who concluded that it was a case of adsorption and not chemical combination, since it follows the so-called adsorption law expressed by an equation of the type $(x/m)^n = kC$, where x/m is the amount of the solute taken up per gram of the adsorbent, C is the concentration in the solution at equilibrium and n and k are constants. In his experiments Biltz found that the values of n and k were respectively 5 and 0.631. In later years, Lockemann and Paucke,³ and Lockemann and Lucius⁴ studied the conditions under which the adsorption of arsenious acid from solution is complete. The results obtained by the latter authors show that a given amount of arsenious acid is removed from solution by a considerably smaller amount of precipitate when an exactly stoichiometric amount of ammonia is used than when twice that amount is used. They also observed that the adsorption of arsenious acid is considerably reduced by the use of potassium hydroxide or sodium hydroxide instead of ammonia. Mecklenburg⁵ worked with ferric hydroxide and arsenious acid in demonstrating his principle of "affine Adsorptionskurven" i. e. adsorption curves, so related, each by a particular factor, to an unit curve, that the ordinate corresponding to any given abscissa on one of the curves may be obtained by multiplying, by the factor, the ordinate on the unit curve corresponding to the given abscissa. He showed that the adsorption curves obtained from differently prepared samples of hydrated ferric oxide were actually related in such a way to an unit curve, which he at first determined for one particular preparation. In a recent paper Boswell and Dickson⁶ have again studied the subject and have come to several interesting conclusions. They used a two-month old sample of precipitated ferric hydroxide and they did not find any ageing effect of the hydroxide on its adsorption power. The adsorption of arsenious acid was found to be diminished by the presence of sodium hydroxide, but the adsorption of sodium hydroxide was found to be increased by the presence of arsenious acid. In supporting further the generalisation of Mecklenburg to the effect that where the adsorption of a compound from solution follows the equation of the type $E = \beta A^p$, p is a constant for the same adsorbing material, and that an adsorbent prepared under various conditions, or of various ages will vary only in the value of β , Boswell and Dickson have shown that p remains constant for different preparations of ferric hydroxide where arsenious oxide alone was used. In Table I the results calculated for various preparations are shown.

TABLE I

Constants for the equation $E = \beta A^p$ for ferric hydroxide

Series	Precipitation temperature	p	β
Boswell and Dickson			
(1) pure As_2O_3		0.210	128
(2) As_2O_3 —constant NaOH		0.284	333
Mecklenburg	1°	0.183	195
Do	11°-12°	0.188	184
Do	23°	0.197	184
Do	45°	0.186	180
Do	51°	0.195	170
Do	60°	0.187	170
Do	98°	0.195	120
Do unit curve	—	0.188	200
Do air-dried	98°	0.195	43
Biltz	—	0.198	170

These results support the conclusions of Mecklenburg to a certain extent. As the results obtained by me are somewhat different, an account now will be given of the effect of ageing, different method of preparation, etc., on the adsorptive power of ferric hydroxide under different conditions.

Experimental method.

The ferric hydroxide was always precipitated at the room temperature (about 25°C), from a 2 N solution of $FeCl_3$ with excess of dilute ammonia, care being taken to avoid any rise in the temperature by immersing the whole vessel in cold water. The precipitate was usually highly gelatinous, and it was washed partly by decantation and finally by dialysis till completely free from chloride. The freshly precipitated substance was dark brown, but when one sample was allowed to "age" under water, after four months it became dull red. All the samples were kept always covered with water. In making the adsorption experiments, 10 cc of this hydroxide was taken out by means of a pipette, and introduced into a 100 cc flask. The necessary amount of the solute was then poured into the flask, and water was added up to the mark. The whole thing was shaken several times at constant intervals and then allowed to settle for a fixed time. The supernatant liquid was then analysed iodometrically in presence of sodium bi-carbonate. Many observations showed that there was no appreciable error in taking out the ferric hydroxide by means of the pipette, the maximum being 0.2 per cent. In course of the investigation, it was found advisable to use a constant quantity of some neutral salt like KCl in the flasks, otherwise a peptisation of the hydroxide took place, and the supernatant liquid became turbid. It was however found out that the presence of this salt exerted no effect on the amount of adsorption by hydrated ferric oxide. In some preliminary cases, ammonium chloride has been used as the salt. Where acids or alkali have been used as the

solute, they were titrated by means of carbonate free alkali or standard acid with phenolphthalein as the indicator. The time of settling was usually 20 hours and the volume 100 cc.

From preliminary experiments it was found that the adsorption results were quite reproducible. In Table II the effect of ammonium chloride is shown.

TABLE II

Concentration of As_2O_3 in grms.	No NH_4Cl	Adsorption in grams.	
		$\text{NH}_4\text{Cl} = .013$ mole litre	$\text{NH}_4\text{Cl} = .02$ mole litre.
0.1578		0.09228	0.09228
0.12624	0.08748		0.08748
0.09468	0.07448	0.07448	0.07448
0.06312	0.06236	0.06236	0.06236

These results show that the addition of ammonium chloride has no effect on the final equilibrium and potassium chloride also behaves similarly. At this place, some experiments were made to test the reversibility of the equilibrium between arsenious acid and ferric hydroxide. Biltz (loc. cit.) has already shown that the equilibrium is reversible and my experiments have also supported it. It will be shown later on that the effect of time on this adsorption is also nil when three hours are allowed for the adsorbent to settle down. In the following table the effect of concentration of the arsenious acid on its adsorption by a fixed amount of ferric hydroxide is shown. The hydroxide is the same as used in the previous experiments.

TABLE III
Adsorption of arsenious acid
wt. of $\text{Fe}_2\text{O}_3 = 0.2645$ grms.

Original concentration As_2O_3 in grms	Concentration after adsorption	Adsorption in grms by 1 gr. adsorbent
0.4901	0.3661	0.4688
0.4593	0.3363	0.4650
0.3977	0.2793	0.4477
0.3367	0.2223	0.4325
0.2840	0.1967	0.4057
0.25248	0.14968	0.3890
0.2209	0.1193	0.3841
0.18936	0.0909	0.3723
0.1578	0.08552	0.3469
0.12624	0.03876	0.3308
0.09468	0.02020	0.2816
0.06312	0.00076	0.2356

The hydroxide used in the above investigation was prepared only a few days before the actual experiment was made. Its colour was dark brown, and this sample was now put inside a stoppered bottle and kept in a dark place for four months in order to investigate the effect of ageing. The temperature

of the outer atmosphere rose about 6° higher during this interval. On opening the vessel after about four months, it was found that the colour of the sample was now dull red, and though the hydroxide was always kept under water, it appeared to have been dehydrated and agglomerated. Though this is curious, it seems to be the only explanation of this remarkable colour change.¹ The weight of ten cubic centimeters of the substance as withdrawn by the pipette remained constant, and in Table IV are the results obtained by using this sample as the adsorbent of arsenious acid is given. Other conditions remain the same:

FIG. 1

TABLE IV

Original conc. of As_2O_3 in grms.	Conc. after adsorption	Adsorption in gms. by 1 gr. of the adsorbent
0.3638	0.30584	0.2192
0.34178	0.28865	0.2008
0.31947	0.26680	0.1992
0.29739	0.24610	0.1939
0.27508	0.22770	0.1792
0.2369	0.19021	0.1765
0.20861	0.16215	0.1757

The results given in Tables III and IV are plotted in Fig. 1. It will be obvious that the ageing has an appreciable effect on the adsorptive power of ferric hydroxide and that the actual amount of adsorption greatly decreases due to this ageing effect. It has already been mentioned that Boswell and Dickson did not find any ageing effect on their ferric hydroxide. My results are therefore different from theirs and it became a matter of interest to investigate this subject further. It has been found that this ageing effect is quite appreciable after the first few days of the preparation of the oxide, but

¹ Weiser: J. Phys. Chem., 24, 286 (1920).

after about 25 days, the effect of ageing is not appreciable. This means that the hydroxide changes at first rather quickly, but after sometime this change is very slow. In the light of these experiments, the result of Boswell and Dickson becomes apparent, for these investigators used a two-month old hydroxide for adsorption experiments. In Table V, the adsorptive power of the fresh hydroxide is compared to that of the aged hydroxide when the original concentration of the arsenious acid is the same. The values have been obtained from the experimental curves.

TABLE V		
Original conc. or As_2O_3 in grms.	Fresh hydroxide	Amount adsorbed by one gram of the aged hydroxide
0.10	0.300	0.0967
0.15	0.347	0.180
0.20	0.373	0.160
0.25	0.397	0.180
0.30	0.417	0.197
0.40	0.447	0.280

It will thus be observed that the amount of adsorption by an old sample of ferric hydroxide is about fifty per cent less than that of the fresh one.

Effect of time.

In all the results given above, the time allowed for the equilibrium to set in has been 20 hours. At this point it became desirable to investigate the effect of time, if any, on the equilibrium concentrations. Many experiments were made which showed that if the hydroxide particles are allowed to settle completely, the final concentration of the solute in the supernatant liquid is always the same. In Table VI is the result obtained with the aged sample.

TABLE VI		
Original conc. of As_2O_3 in grm.	Time 3 hours	Amount adsorbed per gram adsorbent Time 20 hours
0.2369	0.1765	0.1765

This result shows that the equilibrium was reached within three hours, and the adsorption does not change with the increase in the duration of the contact of the solute with the adsorbent.

Experiments with different samples

In the experimental results already recorded, the same material under two different conditions has been examined. It was now thought desirable to investigate whether Mecklenburg's generalisation as to the constancy of the value of the exponential factor in the adsorption equation is true for our samples or not. For this experiment, two other samples of ferric hydroxide were prepared, the method of preparation being almost the same as before. For the sake of convenience the hydroxide already examined will be denoted as sample No. 1, whilst the aged one will be denoted as No. 1a. In Table VII the results obtained with the sample No. 2 are shown.

TABLE VII

$\text{Fe}_2\text{O}_3 = 0.4719 \text{ gr.}$

$\text{NH}_4\text{Cl} = .02 \text{ mole per litre}$

Vol. = 100 cc. Time 20 hours.

Original conc. in grms.	Conc. of the solution after adsorption	Amount adsorbed by 1 grm. adsorbent.
0.7713	0.6365	0.2856
0.7230	0.5896	0.2828
0.6748	0.4429	0.2796
0.4820	0.3522	0.2751
0.4338	0.3051	0.2728
0.3856	0.2621	0.2617
0.3374	0.2176	0.2541

In Table VIII, the results with sample No. 3 is shown. In this experiment, ammonium chloride was replaced by potassium chloride, the concentration of which was 0.05 mole per litre. Potassium chloride however had no effect on the equilibrium between the hydroxide and the arsenious acid. The amount of Fe_2O_3 used was 0.2539 gr. The other conditions remain the same.

TABLE VIII

Original conc. of As_2O_3 grms.	Conc. of the solution after adsorption	Amount adsorbed by 1 grm. adsorbent
0.2892	0.2270	0.2431
0.2410	0.1802	0.2376
0.1928	0.1334	0.2322
0.1446	0.0877	0.2224
0.0984	0.0456	0.1986

In Table IX the results obtained by varying the amount of adsorbent No. 3 have been recorded. The original concentration of the arsenious acid 0.2892 gr. was the same in all cases, the amount of ferric hydroxide actually taken being in each case different. It is interesting to note the change in the actual amount of adsorption calculated per gram of the adsorbent with the change in the amount of the adsorbent taken for experiment. This result is shown in Fig. 2 as No. 3a.

TABLE IX

Amount of adsorbent in grms.	Conc of the solution after adsorption	Amount adsorbed by 1 grm. adsorbent.
—	0.2892	—
0.2559	0.2270	0.2431
0.5118	0.1661	0.2405
0.7677	0.1123	0.2304
1.0236	0.0714	0.2127

In order to make a comparison in the values of the exponential factor of the several samples, the logarithmic curves have been drawn and are given in Fig. 2. Only the simple equation $(x/m)^n = kC$ has been used where x/m is the amount of the solute adsorbed per gram adsorbent and C the concentration of the solution in grms. at equilibrium, n being the exponential constant,

and k the other constant. The abscissa and the ordinate represent the values of $\log x/m$ and $\log C$ respectively, and the values of n have been obtained from the curve, n being the slope of the curve.

It will be seen from Fig. 2, that the logarithmic curves all approximate to straight lines showing thereby that the adsorption equation is applicable in these cases. The values of the constant are shown in Table X. It may be pointed out that in our form of the equation, the value of n is the reciprocal of that used in the form in Mecklenburg's paper.

Sample of hydroxide	TABLE X	
	n	$1/n$
No. 1	5.67	.176
No. 1a	4.51	.221
No. 2	9.51	.105
No. 3	11.43	.087
No. 3a	11.43	.087

Fig. 2

These results reveal two interesting facts. The first is that the exponential n remains only approximately constant when a fresh and an aged sample of the same preparation are used, the difference in the values of k being great. When however different preparations are used, the value of n varies appreciably.

This will be evident when the values of n for samples 1, 2 and 3 are compared. It will also be interesting to note the values of $1/n$ given in Table X and the values of p given in Table I. The difference is so marked that it appears that the conclusion of Mecklenburg is limited in its application. Another interesting fact observed in this connection is that if experiments are made with the same adsorbing material but under different conditions which however do not affect the adsorbent in any way, then the values of both the constants in the adsorption equation remain the same. This will be seen from the curves where results with No. 3 and No. 3a are represented by the same straight lines.¹

It has already been stated that both Lockemann and Lucius (*loc. cit.*) and Boswell and Dickson have found that the presence of caustic alkali decreases the adsorption of arsenious acid considerably. The latter authors further found that though the amount of adsorption of arsenious acid is decreased in presence of caustic alkali, the adsorption of the latter however is increased in the presence of arsenious acid. In view of this curious result some experiments were carried out to determine the adsorption of pure sodium arsenite and sodium hydroxide separately at the same concentration. The sodium arsenite was estimated iodometrically by means of iodine solution in presence of sodium hydrogen carbonate, and the alkali was estimated by means of

¹ Some recent experiments with manganese dioxide show that even this is not true in the case of adsorption of some salts like copper sulphate.

standard hydrochloric acid with phenolphthalein as the indicator. In order to make a comparative study, the adsorption of pure arsenious acid was also investigated side by side with that of sodium arsenite. In the following tables, the results obtained are given. As there was some doubt as to whether simply the arsenite ion or the sodium arsenite as a whole is adsorbed, the values are expressed in terms of iodine. Ammonium chloride was added in the experiments with the arsenite, but no ammonium salt was added when the adsorption of the alkali was determined.

Sample No. 1a—0.2645 gr.	
Original conc. of arsenite in terms of I ₂ milli-equivalents per 100 cc.	Amount of adsorption in terms of I ₂
9.320	1.152
7.767	1.133
6.215	1.067
4.660	1.002

TABLE XII

Adsorption of NaOH of approximately same strength as sodium arsenite.

Same sample of Fe ₂ O ₃	
Original conc. in milli- equivalents	Adsorption in milli-equivalents
9.210	0.2351
7.676	0.2250
6.141	0.2150
4.606	0.2050

TABLE XIII

Sample 2—0.4719 gr	
Original conc. of arsenite in terms of I ₂ —milli equivalents	Adsorption in terms of iodine
9.320	2.757
7.767	2.715
6.215	2.673
4.660	2.583

The results given above show that sodium arsenite is highly adsorbed by ferric hydroxide, and the adsorption of alkali is also appreciable. When however a comparison was made between the adsorption values of arsenite and arsenious acid, an apparently anomalous result was obtained. It was found that with the sample of ferric hydroxide No. 1a, with dilute arsenite the adsorption is greater than that of pure arsenious acid of the same concentrations in terms of iodine. With higher arsenite concentration however, the adsorption value becomes less than that of pure arsenious acid. With sample No. 2, the adsorption of arsenite was always higher than that of pure arsenious acid in the concentration studied. Since sodium arsenite hydrolyses to a great extent in water, it is probably that when sodium arsenite is used as the solute, actually the simultaneous adsorption of alkali and arsenious acid by hydrated ferric oxide is observed. Hence when alkali is present, the adsorp-

tion of arsenious acid should in general decrease owing to the simultaneous adsorption of the alkali. As a matter of fact this has been observed by a number of investigators already cited. It is rather difficult to explain however the contradictory results already recorded, and further experiments are being done to arrive at a satisfactory conclusion.¹

In the foregoing pages, I have discussed the effect of ageing, different method of preparation of the adsorbent, the effect of neutral salts, the effect of change in the concentration of the solute, and the effect of varying the amount of the same adsorbent, on the amount of adsorption of arsenious acid. All these experiments were however done at a constant volume of 100 cc. In the following tables, some more results dealing with the effect of volume of the solution on adsorption are given. In these experiments, ferric hydroxide sample No. 3 has been used, the weight of the adsorbent being 0.2559 gr. and potassium chloride has been used instead of ammonium chloride.

Effect of volume when the normality of the acids is constant. The actual amount of solute is thus different.

TABLE XIV

Adsorption of As_2O_3 .	Concentration = 0.1928 gr. per 100 cc
Volume	Amount adsorbed in gms.
10 cc	0.05943
50 cc	0.05604

TABLE XV

Adsorption of sulphuric acid.	Concentration = 0.5491 milli-equivalent per 100 cc.
Volume	Adsorption in milli-equivalents
100 cc	0.3792
50 cc	0.2456

TABLE XVI

Adsorption of benzoic acid	Concentration = 0.7358 milli-equivalents per 100 cc.
Volume	Adsorption in milli-equivalents.
100 cc	0.3301
50 cc	0.2736

Effect of volume when the total solute is same. The strength in terms of normality is thus different.

TABLE XVII

Adsorption of As_2O_3	Concentration = 0.0964 gr.
Volume	Amount adsorbed in grms.
100 cc	0.05077
50 cc	0.056628

¹ New experiments show that this behaviour is shown by other samples of hydroxide also when Merck's sodium arsenite is used. By working with sodium arsenite prepared by mixing caustic soda with arsenious acid, the results of Foswell and Dickson have been confirmed.

TABLE XVIII

Adsorption of benzoic acid. .Concentration = 0.3679

Volume	milliequivalents. Adsorption in milli- equivalents.
100 cc	0.2641
50 cc	0.2736

These results emphasise the importance of the volume of the solution in which adsorption is studied. It will be observed that when the total solute is constant, the less the volume, the greater is the adsorption. Whilst with the same normality of the solution but different absolute amount of the solute, the amount of adsorption increases with the volume of the solution. In other words it becomes proportional to the quantity of the solute.

Having thus studied the adsorptive power of hydrated ferric oxide under various change of conditions, a systematic study of the adsorption of different mineral and organic acids was made. Since in these preliminary researches it was observed that the amount and the nature of the hydrated ferric oxide exert a considerable effect on its adsorptive capacity, it was necessary to use the same amount of ferric hydroxide of the same preparation in a constant volume of the solution for a comparative study. For this reason, the ferric hydrogen sample No. 3 has been used in all the experiments to be given in the next paper.

CELL MITOSIS

BY WILDER D. BANCROFT AND CHARLES GURCHOT

Some years ago, our attention was called by Professor Chambers and Mr. I. H. Page of the Cornell Medical College to the fact that the physical chemistry of cell division was in a rather confused state, and we were asked to give our opinion as to the general theory. All the experiments were done by Mr. Gurchot.

The general problem can be stated in a very simple manner. If we have a drop of liquid and if we lower the surface tension locally at two opposite poles, will the drop constrict and tend to break into two drops at the equator where the surface tension is relatively high or along a line passing through the poles, where the surface tension is relatively low?

In 1876 Bütschli stated that such a drop would split along the equator, it being pinched in two by the action of the relatively high surface tension along that line. T. Brailsford Robertson¹ has put forward and defended the opposing view that the drop pulls apart where the surface tension is the lowest. "In a continuous fluid surface of variable tension the regions of high superficial tension must be convex to the outer medium while those of low superficial tension must be concave to the outer medium. If this concavity occurs all round an equatorial circumference a dumb-bell shaped surface will be produced of which the equatorial (approximately cylindrical) portion may be short or long according to whether the slope of the cleft is steep or gradual. If this process (reduction of tension) proceeds sufficiently far to cause the length of the equatorial cylindrical portion to become equal to its circumference, it will break and one drop will split into two."

The flaw in this reasoning is the assumption that an area of relatively high surface tension must be convex to the outside medium. It is true that a drop of one liquid at the bottom of a beaker filled with another liquid will be more nearly spherical, the higher the surface tension. With a lower surface tension the drop will flatten out more under the influence of gravity. The flattened drop is less convex than the spherical one on the top and more convex at the sides—a point which Robertson has overlooked. Robertson then introduces the tacit assumption that a further lowering of the surface tension would cause a greater effect in the same direction and that, having gone from convex to flat on the upper side, it will then go from flat to concave. In the first place, it will not do that. The drop will spread out thinner and thinner, until it forms a layer one, or at most two, molecules thick, after which it will spread no more, so far as we now know. In the second place, this has very little to do with the case in question, because we are not dealing with localized differences of surface tension except in so far as the action of gravity sets up different surface tensions in different parts of the drop.

¹ Archiv Entwicklungsmechanik, 27, 29 (1909); 32, 368 (1911); 35, 692 (1913).

Robertson offered some experiments with olive oil in support of his views. He placed a thread soaked in alkali round a drop of oil submerged in water by addition of chloroform. Since the alkali reacts with the olive oil to form soap, this lowers the surface tension. The drop separates into two drops along the line of the thread, as though it had been cut in two by the thread. At first sight this experiment seems conclusive.

McClendon¹ supports Bütschli's views that a drop of liquid will tend to split into two drops along the line where the surface tension is relatively highest. He considers "that in Robertson's experiment the oil drop is divided by the gravitation of the thread which has been soaked in an alkaline solution. The alkali reduces the surface tension, thus reducing the resistance to division, and thus allows division by a thread of less weight than would otherwise be necessary. This seems to be a just criticism because Robertson² admits that "light threads of sewing-cotton cannot be employed with success as they float upon the top of the oil-droplet without sinking into it; the diminution in tension is, consequently, not equatorial. I obtain the best results with linen threads 0.4 mm. in diameter. Linen threads 0.2 mm. in diameter only, float upon the surfaces of the drops and rarely cause division." Robertson accounts for this fact in a different way. He says, when discussing the weight of the thread, that "it is not sufficient that a small sector of an equatorial circumference of the drop be touched by alkali; it is necessary that soap should be formed in the periphery of an equatorial plane. This cannot occur unless the weight of the thread is sufficient to cause it to sink a little way into the drop." It apparently did not occur to Robertson that he could soak the thread in soap instead of in alkali.

McClendon did a set of experiments of his own. "It is not my ambition to imitate cell division exactly with a model; but an analysis of the following experiment may throw some light on what happens when a cell divides. A stender dish is half filled with distilled water and a funnel inserted so that the stem reaches the bottom. A saturated solution of pure sodium chloride in distilled water is poured very slowly into the funnel so that the salt solution comes to lie beneath the pure water without much mixing. About 1 cc. of the chloroform-oil mixture is poured in, so that it forms a drop suspended in the liquid. Two pipettes are filled with fifth-normal sodium chloride solution and quickly introduced into the water, and the alkali allowed to flow gently against opposite poles of the drop. If the alkali reaches both poles at the same time and in the same quantity, the drop elongates along the polar axis and usually constricts into an hour-glass shape. It often divides into two at the constriction. The conditions necessary for complete division are very limited, as is explained in the following analysis of the experiment.

"The alkali reduces the surface tension at the poles and the pressure [?] inside the drop causes a bulging of these regions. At the same time the polar

¹ *Am. J. Physiol.*, 27, 240 (1910); *Archiv Entwicklungsmechanik*, 34, 263 (1912); 37, 233 (1913).

² *Archiv Entwicklungsmechanik* 35, 695 (1913)

surface films spread and the equatorial surface film contracts, producing vortex movements in the drop and in the medium. These movements may be demonstrated by mixing a little soot with oil and a few carmine grains with the water. The surface currents carry the alkali toward the equator and enlarge the polar regions of reduced tension. The rapid fall in the internal pressure caused by the rapid enlargement of the surfaces of low tension allows a constriction of the equatorial region. The equatorial surface is not concave (as Robertson intimates) but remains convex until the meridional concaveness equals the equatorial convexness. When the surfaces of reduced tension have expanded until the area of high tension forms but a narrow band around the constricted equator, this band acts like an isolated band of a tension equal to the tension of its surface minus the tension of the surface of the polar regions. The entire force of this residual tension is exerted toward the division of the drop. However, the completion of the division takes time, and the band is reduced rapidly in width by the spreading of the alkaline surfaces. If the constriction is not completed before the alkali spreads over the whole drop, the drop returns to a spherical shape. Therefore it is unusual that a complete division of the drop occurs. Failure to perform this experiment is due to lack of dexterity. The smaller the drop, the (relatively) greater is the dexterity required. Pipettes with capillary openings are more easily controlled, and the concentration of alkali may be increased to compensate for reduced quantity, but it should not be heavier than the salt solution."

Robertson says: "I have repeated this experiment of McClendon's a number of times and under a variety of conditions and I regret to have to admit that I have hitherto been unable to obtain precisely the appearance which he illustrates. Doubtless this is due to some defect in my technique; but, granting this to be the case, the phenomenon described by McClendon is only indirectly due to molecular forces and does not bear upon the mechanics of cell division at all.

"Briefly, what I observe in repeating McClendon's experiment is the following:—as soon as the alkali touches the drop of oil (which is resting upon the flat bottom of a glass vessel), the drop ceases to be spherical and flattens quite suddenly. Transiently, the flattened mass may bulge in irregular shapes towards the pipettes; but the usual effect (if the alkali be not too strong) which immediately succeeds this is a gathering up of one or other or both of the equatorial extremities of the mass into a more or less globular form and an elongation of the mass equatorially in a direction perpendicular to the line joining the openings of the pipettes. If this takes place at both equatorial extremities at once, division of the mass into two may actually occur in a plane perpendicular to the plane of division which is depicted by McClendon.

"It is easy to understand what is really taking place under these circumstances. The forces acting upon a drop which is resting upon a flat surface are not purely molecular; gravity is also acting and tending to flatten the drop and cause flowing in a lateral direction. This tendency is resisted by the surface tension of the drop; but, if the superficial tension be reduced over any

considerable area, bulging will occur and the fluid will flow towards the side of reduced tension because the centre of gravity of the fluid mass is lowered thereby. Molecular forces, although reduced, are still effective, however, and, if the mass be not too large or the tension too much reduced, the region of high tension will become highly curved and the regions of low tension indented in accordance with the principles already made clear, so that the fluid mass becomes elongated equatorially in a direction perpendicular to the line joining the openings of the pipettes.

"That the flowing and bulging of the drop towards the region of reduced tension is really due to gravity and not to molecular forces is readily seen from the following experiment. Saturated sodium chloride solution is poured into a glass cylinder until it approaches near to the top, and then the cylinder is inclined and distilled water poured gently down the side so as to avoid so far as possible the mixing of the two fluids. In this way we obtain a cylinder of fluid of continuously varying density increasing from above down. On now introducing into this, drops of the chloroform-oil mixture described above, we find that they float in the fluid at a little distance below the surface, where the fluid is of the same density as the drop. Under these circumstances the drop behaves as if it were weightless; only molecular forces affect it and gravity has no action upon it.¹ On now applying tenth-normal caustic soda to two poles of such a drop by means of pipettes, we find that no bulging of the drop towards the pipettes appears at all; on the contrary, the poles flatten and the equatorial region becomes highly curved, so that the drop is converted into a disk of which the long diameters are perpendicular to the line joining the orifices of the pipettes. If tenth-normal caustic soda be employed, the result is in no way different. The rationale of this phenomenon will be apparent from what has preceded."

This apparently brings the matter to the point that a mixture of olive oil and chloroform behaves one way for McClendon and another way for Robertson, in each case behaving as the experimenter thinks it should theoretically. It is a beautiful instance of how difficult it is to tell just what an experiment really shows.

Some light has been thrown on the subject by the experiments of Spek,² who agrees with McClendon that a drop tends to split into two drops along the line at which the surface tension is relatively highest. Spek worked both with weighted oil drops which lay on the bottom of the beaker and with drops which stayed suspended. While both kinds of drops give the same results in general, he thinks that it is more satisfactory to work with drops on the bottom of the beaker. In his first experiment he let a caustic soda solution flow out of two pipettes and impinge on opposite sides of an oil drop which had been colored with alkanna. Under these conditions the formation of a film of solid soap on the poles of the drop becomes visible, and he considers this objection-

¹ Cf. J. Plateau: "Statique des liquides soumis aux seules forces moléculaires," 2 (1873); Mach: "The Science of Mechanics," 384 (1902).

² Archiv Entwicklungsmechanik, 44, 5 (1918).

able. He therefore touched opposite sides of the drop with crystals of sodium carbonate. In this way he was able to make drops of bergamot oil, of an oil used for night lights and mixed with olive oil, of castor oil, of cedar wood oil, and of pure oleic acid divide at the equator, the best results being obtained with the mixture of the night-light oil and olive oil, and with bergamot oil. When drops of mercury in dilute acid were touched at opposite points with crystals of potassium bichromate, the mercury divided along the line of highest (relative) surface tension.

Spek was also able to confirm Robertson's apparently contradictory results. "I was never able to obtain a constriction at the equator with drops of pure olive oil suspended in water. Regardless whether one touched the drop with one or with two crystals of soda, the drop always separated into a lighter and a heavier half. If one touches the drop on the right and left with soda crystals, the plane of division was always a horizontal one passing through the two poles, just as Robertson describes it. If the differences in the densities happen not to be sufficient to cause a splitting, the drop stretches in a vertical direction. The explanation of this contradictory result is undoubtedly to be found in a special behavior of the olive oil [or of the olive oil soap]. None of the other oils studied by me and not even mixtures of olive oil with other oils showed this separation into a higher half. With the other oils the effects due to differences of surface tension were not obscured by disturbing circumstances as in the case of olive oil.

"I doubt, therefore, whether McClendon used pure olive oil. If he did—and I don't know what really pure olive oil is—it had different properties from the oil used by Robertson and by me."

Without making special experiments, it is impossible to say what the difference was between the olive oil used by Robertson and Spek on the one hand and by McClendon on the other hand. It may have been a lack of free acid or a difference in stearin content. It seems to us that Spek has settled the matter satisfactorily and that a liquid drop does tend to divide along the line of the highest (relative) surface tension. Since the theory of the matter did not seem clear to Professor Chambers nearly seven years after the publication of Spek's paper, it seemed desirable to repeat some of Robertson's work.

Before describing the experiments done in the Cornell laboratory, there is another point of disagreement between Robertson and McClendon which should be mentioned. McClendon¹ says: "The mechanics of cell division may be illustrated by a more tangible model. A rubber balloon is inflated with air and attains a spherical shape. The rubber may represent the surface film and with uniform thickness of rubber we obtain uniform tension and spherical shape. If the equator of the balloon is re-inforced with a rubber band, the tension along the equator is increased and the balloon is constricted equatorially."

Robertson² says that McClendon forgets that a rubber balloon can in no way afford an analogy to a fluid surface because, in the first place, adjacent

¹ Archiv Entwicklungsmechanik, 34, 265, (1912).

² Archiv Entwicklungsmechanik, 34, 701 (1918).

non-continuous portions of its surface do not attract one another and, in the second place, the tension of rubber varies with the degree to which it, while that of a surface does not. The falsity¹ of this analogy has repeatedly been insisted upon by physicists."

An analogy may not be complete in every detail and perhaps never is; but that is no reason why an analogy may not be valuable. It is a reason why one must guard against falling into error when making use of an analogy; but it is quite unjustifiable to say that a rubber balloon can in no way afford an analogy to a fluid surface.

In most of the experiments done in the Cornell laboratory, advantage was taken of the technique developed by Robertson and by McClendon, but with modifications wherever necessary. For instance, McClendon used rancid olive oil, which is a bit indefinite. When olive oil has been allowed to become rancid spontaneously, one cannot be sure about the amount of free acid in a drop of oil. An insufficient amount will keep the drop from dividing rapidly; it may divide very slowly or even not at all. Consequently the oil used was made rancid artificially by adding oleic acid. Ten percent free acid was found to work very satisfactorily. Chloroform was also added, to increase the density of the drops of oil. A drop of oil was placed in a large dish of distilled water and enough sodium chloride solution added to enable the drop to be suspended. The salt solution was mixed thoroughly with the water so that there was no concentrated bottom layer.

Robertson's experiment of splitting a drop with a thread impregnated with alkali was performed first. As Robertson does it, a thread of given diameter and impregnated with a sodium hydroxide solution of a given concentration is looped around the middle of an oil drop situated at approximately half a centimeter below the surface of the water solution. The experiment is not an easy one to do, and it is rather unfortunate that such a painstaking technique was developed, for it will be shown that Robertson's experiment proves nothing whatever. This conclusion is based partly on the conviction that any experiment which can be interpreted from several antagonistic points of view is valueless in proving one to the exclusion of the others. In the first place, if on coming in contact with the impregnated thread, the drop contracts to some extent, the loop of thread must be made smaller to keep pace with the contraction or the contraction will cease and the drop will divide. To do this and at the same time to be sure that the drop is not cut by the thread is something of an achievement. If Robertson's technique is followed strictly, the case is much worse. On beginning the experiment Robertson tightens the loop just sufficiently to embed the impregnated thread in the drop. Inevitably a soap film is formed along the path of the thread and also below by diffusion of the alkali toward the center of the drop. The soap film dissolves and, obviously, the drop splits at least as far down as the thread. If the thread is pulled tight, so as to embed it in the drop completely, more, the splitting will continue and eventually the drop will split completely.

¹ Cf. for example, C. M. Minchin: "Hydrostatics and Elementary Hydrokinetics, 338 (1892).

in two. Therefore Robertson's method of decreasing the surface tension of a drop at the equator may very likely cause a drop to divide; but probably surface tension has nothing whatever to do with it. Or if it has, there is no way of finding it out. But suppose the drop should divide when the thread merely touches the equator; and one is sure that the drop has not been strangled. Here an antagonist to the "equatorial theory" can suggest that a momentary bulging of the drop in the region of the equator has caused the thread to become ever so slightly embedded and the drop will divide in the manner shown above. As a matter of fact about one per cent of the number of drops experimented upon were observed to divide.

McClendon's experiment does not seem to be open to serious objections and it was the next to be tried. Here the surface tension is lowered in the region of the poles. Instead of resorting to pipettes which allow dilute caustic soda to flow against the opposite poles of the drop, glass tubes were used (inside bore 2 mm) bent into right angles and plugged with cotton at the end intended to come in contact with the drop. The tubes were filled to the same level with concentrated caustic soda solution. The ends were brought barely in contact with the poles. The caustic soda solution oozed out slowly through the cotton plugs and the drop divided, almost immediately in the majority of cases, into two equal or unequal halves without any appendages remaining as a reminiscence of a former attachment. This experiment can be performed with comparative ease once everything has been properly adjusted. There can be no question concerning its significance. A rather amusing, even perhaps a little malicious, variation of the above experiment, is interesting. If a bare thread is looped around the equator of the drop and if, at the same time, the surface tension is reduced at the poles the drop will divide in the usual way. The paradox here is that if some opponents of the "equatorial theory" feel impelled not to recognize the validity of the foregoing experiment they are called upon to explain the fact that an ordinary thread looped about the equator of an oil-drop causes the latter to divide.

But everything does not rest here. If a drop divides because the surface tension is reduced at the poles there is yet a phenomenon which remains to be demonstrated. If the drop really divides, it does so by virtue of the fact that the surface skin is stretched toward the equator since the tension is raised there. Eventually the drop is squeezed in two. Consequently, a point on the surface near a pole should be seen to move toward the equator during the process of division. If McClendon's experiment is performed in a medium containing commercial sodium chloride instead of the pure salt the phenomenon is demonstrated very easily. The commercial salt contains calcium or magnesium salts or both. These react with the caustic soda and enough calcium or magnesium base is produced to form a cap of insoluble soap at the poles of the drop. When caustic soda is applied at the poles as before, the insoluble soap films are pulled instantly over the surface of the drop and meet in the middle to form a white equatorial band. This effect takes place to the same extent whether the drop is touched at the poles only momentarily,

so as to prevent complete division, or whether the process is allowed to go to completion. No such bad effect was observed when pure sodium chloride was used in the immersing medium.

Here it may be well to recall an experiment performed before all the others and which, although perhaps not conclusive in its results, nevertheless showed interesting possibilities. A thin-walled rubber balloon was filled with about 100 cc of distilled water. This simulated a large drop or a large cell covered with a membrane. The balloon was immersed in a three-layer liquid contained in a tall vessel. The bottom layer was carbon bisulphide, the middle one distilled water and xylene made up the top layer. The south pole of the balloon touched the carbon bisulphide layer and the north pole touched the xylene layer. Since xylene and carbon bisulphide both emulsify rubber there resulted a lowering of the surface tension at the poles of the balloon. Unfortunately, carbon bisulphide emulsifies rubber too quickly and the balloon burst. The procedure was repeated but this time xylene alone was used and now the surface tension was reduced at one pole only. After having stood for about fifteen minutes the once spherical balloon now assumed an oval shape. The apex of the oval rested on the bottom of the vessel and the wide portion rested against the xylene layer-part of the balloon being actually immersed in the layer. It should be pointed out that, notwithstanding the hydrostatic pressure, the water in the balloon was squeezed toward the region of lessened surface tension. Here was an indication that the bulging of a drop in the direction of lessened surface tension is at least not an untenable hypothesis. If this last experiment is only an indication of where the truth may lie, the insoluble soap film experiment leaves no room for doubt about where the truth does lie.

The experimental part of this manuscript was sent to Professor Chambers and Mr. Page early in 1925 and it is a pleasure to add a few paragraphs written by Mr. Page. "We are now in a position to examine the evidence as demonstrated by observation of the living cell during the act of cleavage, for and against the two theories of cellular division.

"A brief description of the process will offer a basis for comparison with the facts observed in the dividing oil drop. Not long before division occurs, the viscosity of the protoplasm decreases markedly as demonstrated by Chambers¹ with the microdissection needle, and by Heilbrunn² using the centrifuge method. Active Brownian movement is set up in the region of the furrow which is yet another indication of this decrease in viscosity. That this viscosity change is important as a precursor to interfacial tension changes cannot be doubted. Further, Just³ has shown by the use of cytolysis by hypotonic solutions that the polar region becomes the point of least resistance to the osmotic bulging of the egg. Here we have an indication that the pole is the region of low resistivity. Van Beeden⁴ made the interesting observation

¹ J. Exp. Zool., 23, 483 (1917).

² J. Exp. Zool., 34, 417 (1921).

³ Am. J. Physiol., 61, 505 (1922).

⁴ Bull. Acad. roy. Belg., 41 (1883).

that the *Ascaris* egg before division shows an outward bulging to form more or less distinct lobes, almost amoeboid in aspect at the two poles. Preceding and concomitant with these phenomena the development of the two asters and spindle forming the amphiaser occurs. The egg elongates ("karyokinetic elongation") as the amphiaser attains maximum size. The cleavage furrow now cuts the karyokinetic axis at right angles. However, it does not appear essential that the aster be present inasmuch as constriction division may occur in anastral types such, for example, as noted by Farr¹ in pollen forming divisions of various dicotyledonous plants. Particularly significant to note is that a peripheral flow occurs towards and not away from the equator. Thus in *Arbacia* eggs pigment granules collect around the cleavage furrow in such a way as to demonstrate strikingly this type of viscous flow. Spek² especially has studied these vortical currents in many types of living eggs on division. We see that the flow is away from the area of low to one of higher tension precisely as in the oil experiment in which an insoluble calcium soap was formed at the poles. It will be recalled that in this experiment the soap cap migrated to the equator to form a white band around that region, the flow being toward the area of greater tension, namely the equator.

"Bütschli³ in 1876 suggested that division was brought about by an increase in interfacial tension subsequent to nuclear division in the equatorial region of the egg. He subsequently elaborated this thesis with little change in the principles involved.

"We are forced to the conclusion from the preceding experimental work that the lowering of interfacial tension at the poles accounts for the division of an oil drop under the stated experimental conditions. Insofar as the dividing oil drop parallels the cleavage of the cell we may believe that similar forces are involved in this latter process. Within defined limits this physical system does mimic fission division."

The general conclusion to be drawn from this paper is that Bütschli, McClendon, and Spek were right and that Robertson was wrong. When the surface tension of a drop of liquid is lowered locally at two opposite points or poles, the drop tends to divide equatorially, along the line of highest (relative) surface tension. It is literally pinched in two by the contraction along the line of the highest (relative) surface tension and it consequently bulges at the poles, which are, by definition, the points of lowest (relative) surface tension.

In view of the abnormal results which Robertson and Spek obtained with their so-called pure olive oils and in view of the apparent effect which the nature of the soap has, these experiments should be repeated with caustic potash substituted for caustic soda or potassium carbonate substituted for sodium carbonate. It would also be well to try substituting a solid soap or a soap solution for the corresponding alkali. Although these experiments are both interesting and desirable, they are not necessary to the purpose of this paper and consequently have not been done by us.

SOME PHYSICAL-CHEMICAL PROPERTIES OF MIXTURES OF ACETONE AND ISO-PROPYL ALCOHOL

BY GEORGE S. PARKS AND CLARE S. CHAFFEE

A few years ago, as a preliminary to a study of the equilibrium between acetone, hydrogen and iso-propyl alcohol, some information was needed concerning the physical-chemical properties of liquid mixtures of acetone and iso-propyl alcohol. In the absence of any such data, the investigation to be described in the present paper was undertaken. This particular study is the more interesting because of the recent investigations¹ in this laboratory of the three binary systems formed from ethyl, normal propyl, and iso-propyl alcohols.

These three binary systems were found to approximate to the requirements of an ideal or "perfect" solution to a remarkable degree. Thus the process of forming the various solutions was accompanied by a very small heat effect, the maximum ΔH values being $+4.8$, -12.7 and -10.1 calories per mole of resulting mixture in the respective cases of the ethyl-*n*-propyl alcohol system, the ethyl-iso-propyl alcohol system and the *n*-propyl-iso-propyl alcohol system. The corresponding volume changes averaged $-.025\%$, $-.010\%$ and $-.008\%$. The measured vapor pressures for the three systems agreed within the limits of experimental error with the ideal values calculated by Raoult's law. The viscosities approximated in magnitude to the requirements of Kendall's "cube-root" equation,² the respective deviations averaging only $+.7\%$, $-.4\%$ and $+.7\%$. All these results, of course, are not especially surprising, inasmuch as the three liquids involved are closely related alcohols of approximately the same polarity and internal pressure.

However, in the pair of substances under consideration in the present paper we have a somewhat different situation. One is an alcohol and the other a ketone, the second being the dehydrogenation product of the first. Moreover, while both liquids might be classed as moderately polar, a study of the values in Table I for dielectric constant, capillary constant, and association factor indicates that the alcohol is decidedly the more polar and the more abnormal of the two. As far as relative internal pressures are concerned, the difference is even more striking. Hence, in view of these important factors—chemical dissimilarity, different degrees of polarity, and inequality of internal pressures—it might reasonably be predicted that this binary system would exhibit marked departures from the behavior of the perfect solution. And such was found to be the case.

(CH ₃) ₂ CHOH	26.	1.05	2.86	2.49

Experimental

Purification of Substances. C. P. materials served as the starting point in preparing the acetone and iso-propyl alcohol for the present investigation. To remove possible traces of methanol and water, the C. P. acetone was treated with anhydrous calcium chloride at the rate of 200 gm. per liter. The resulting mixture was allowed to stand for several days, with occasional shaking, and was then distilled. The product thus obtained was further treated with a small quantity of anhydrous calcium chloride and carefully fractionated. The middle portion, representing about 50% of the total and boiling between 56.10° and 56.24°, was selected for use in the measurements. Its density was 0.7855 at 25°/4°, a result which compares favorably with the two values for 100% acetone, 0.7863 and 0.7849, given in the Landolt-Börnstein "Tabellen."

The iso-propyl alcohol was first dehydrated by two distillations over lime in the ordinary manner and was then carefully fractionated. The final product had a density of 0.78130 at 25°/4°, which corresponds to 99.8% alcohol on the basis of Brunel's value⁴ of 0.78084 for 100% and the variation per 1% of water of 0.00230 obtained by Lebo.⁵

Determination of Heat of Mixing. The pure liquids thus prepared were used in making a number of mixtures, which had the designations and compositions represented in Columns 1, 2 and 3 of Table II.

In the course of the preparation of these solutions the heat of mixing was determined at an average temperature of 20° C. The method employed for this measurement was somewhat different from that described by Parks and Schwenck and should give more accurate results. In any particular determination the proper weight of the component which was to be present in greater quantity was placed in a 400 cc Dewar jar, Fig. 1, equipped with a calibrated thermometer accurate to .01°, a stirrer of the propeller type and a tightly-fitting cork cover to exclude moisture. The required weight of the other component was then placed in a small copper container, A, of about 60 cc capacity, which had a bent outlet tube extending upward from its bottom in

¹ Landolt-Börnstein-Roth-Scheel: "Tabellen," pp. 1036-1037 (1923).

² Ramsay and Shields: Z. physik. Chem., 12, 468 (1893).

³ Mortimer (J. Am. Chem. Soc., 45, 640, 1923), gives 1.32 and 2.90 for the respective internal pressures of acetone and ethyl alcohol, relative to that of naphthalene as standard. Since Parks and Kelley found that the internal pressure of iso-propyl alcohol was, as the average of several different modes of calculation, about 14% below that of ethyl alcohol, we have accordingly reduced the value 2.90 by 14% and in this way have obtained 2.49 for iso-propyl alcohol.

⁴ Brunel: J. Am. Chem. Soc., 45, 1336 (1923).

⁵ Lebo: J. Am. Chem. Soc., 43, 1006 (1921).

such a way that it could be kept nearly full. This container occupied a position in the lower part of the Dewar jar and thus the two liquids to be mixed were brought to the same initial temperature. When this condition had been reached, the contents of the copper vessel were forced over into the Dewar jar outside by a stream of air entering the container via the upper entry tube. The air used for this purpose had been previously saturated with acetone or alcohol, as the case might be, in order to avoid any cooling effect due to vaporization within the calorimeter system. The resulting mixture was immediately stirred for two minutes at a rate of 70 R. P. M. and then allowed to stand for a similar period after which the final temperature was taken. By at once repeating the stirring and waiting interval and again reading the thermometer, the temperature correction due to stirring, heat exchanges with the surroundings, etc., was obtained. The corrected temperature change was then used for calculating the heat effect in producing one mole of the solution under consideration. This calculation was made in the usual way, by using 16 calories as the heat capacity of the calorimeter and the values of Parks and Kelley¹ for the specific heats of pure acetone and iso-propyl alcohol, respectively. The heat capacity of each mixture was taken as the sum of the heat capacities of the pure components, a procedure which is strictly accurate only in case there is no deviation from the laws of the perfect solution.

The results, which are good to 5% or better, are given in Table II and are represented graphically in Fig. 2. The process of forming the various solutions took place with the absorption of considerable heat—an indication that we are dealing with solutions that are far from perfect. In the case of the equimolal mixture this heat absorption reached a maximum value of 387 calories, equivalent to a temperature lowering of 11.7°.

Densities and Refractive Indices. The densities of the liquids were next determined in the usual manner, a specific gravity bottle of 35 cc. capacity being used for this purpose. All weighings were corrected for the buoyancy of the air, and the final values appear in the second column of Table III.

FIG. 1

The Calorimeter for the Determination of the Heats of Mixing.

¹ Parks and Kelley: J. Am. Chem. Soc., 47, 2091 (1925).

In the formation of a perfect solution the resulting volume should be equal to the sum of the original volumes of the components involved, or in terms of densities the relationship is

$$\frac{100}{D} = \frac{1}{d_1} P_1 + \frac{1}{d_2} P_2$$

where d_1 and d_2 are the densities of the components in the pure state, P_1 and P_2 are their corresponding weight percentages in the resulting solution and D is the density of the solution. Using this equation, we have calculated the densities which appear in Column 3 of the table. These values average about 0.3% greater than the observed densities of Column 2; in other words, there is actually a very appreciable volume increase accompanying the formation of these solutions.

The refractive indices (Table III, Column 4) for sodium light were then determined with a Zeiss-Pulfrich refractometer, the method of Moore¹ for temperature measurement being employed. These observed results fall on a curve which runs below that of the values calculated on the basis of a straight-

FIG. 2

Heat of Mixing plotted against Mole Fraction of Iso-Propyl Alcohol.

line relationship between the index of refraction and the composition by weight of the solution. Measurement of the index of refraction provides an easy and rapid method of analyzing an unknown mixture of acetone and iso-propyl alcohol. As the instrument used could be read with a precision of ± 1 minute and the refractive angles for the two pure substances differ by 182 minutes, the accuracy of the method is about 0.5%.

Vapor Composition at 25° C. The composition of the vapor phase in equilibrium with the solution at 25° C was next determined. This was accomplished by passing air (freed from water and carbon dioxide) through a series of three bubblers, each containing about 20 cc of the mixture under consideration. The air thus saturated with the vapor of a mixture was then passed through a condensing tube immersed in liquid air; the alcohol-acetone vapor separated out as a solid glass on the walls of this tube and, when about 1 cc of distillate had been collected, was analyzed by measurement of its refractive index. The results appear in the third column of Table IV.

Vapor Pressures at 25° C. The vapor pressures at 25° C were also measured in the case of several representative liquids. The method employed for this purpose was as follows. In each case a 5 cc sample of the liquid under consideration was introduced into a small bulb which was connected to a mercury manometer. The air in and above this liquid was removed by a pump consisting of activated charcoal immersed in liquid air and the bulb and manometer system were then sealed off from the outside atmosphere. During the pumping process the liquid in the bulb was protected from vaporization by its immersion in a bath of liquid air, at the temperature of which its vapor

pressure was negligible. The bulb and contents were then brought to a temperature of 25° C and the vapor pressure of the liquid was measured on the manometer by means of a cathetometer.

TABLE IV
Vapor Composition at 25° C

Liquid	Mol Fraction of Iso-Propyl Alcohol	
	In the original liquid	In the vapor
2A	.152	.108
2B	.161	.090
3A	.292	.137
3B	.302	.137
4A	.452	.172
4B	.486	.202
4C	.488	.197
5A	.661	.265
6A	.812	.390
6B	.849	.422

The results appear in Table V, Column 3. With the mixtures the results in some cases may possibly involve errors as great as 2 or 3%, owing to a residue of dissolved air in the liquid or possibly to a slight change in composition of the liquid during the pumping process. In the cases of pure acetone and pure iso-propyl alcohol these errors were entirely eliminated, since by a process of partial evaporation of the liquid all dissolved air could be pumped off without the risk of a change in composition. Our result for acetone at 25° agrees well with the value 226.3, recently obtained by Mathews¹ in a very careful investigation. For iso-propyl alcohol our present result is almost identical with that of an earlier measurement² in this laboratory.

² Parks and Kelley: J. Phys. Chem., 29, 730 (1925).

For each component in a given mixture the partial pressure is simply the product of its mole fraction in the vapor phase and the total pressure of the solution. Accordingly, from the experimental data in Tables IV and V the partial pressures of the acetone and iso-propyl alcohol in the various solutions were calculated. These results appear in Columns 2 and 4 of the following table. The "ideal" pressures in all cases were derived on the assumption of Raoult's law:

$$P_A = N_A P_{oA}$$

where P_A and N_A are respectively the partial pressure and the mol fraction of component A in a given solution and P_{oA} is its vapor pressure in the pure state.

The data for the partial and total pressures are represented graphically in Fig. 3. It is obvious that the solutions show a marked positive deviation from Raoult's law, amounting in the case of an equimolal mixture to about 21%.

Viscosities. We also determined the viscosities of the various liquids, using two Oswald viscosimeters in a 25° C thermostat, regulated to .01°. The time was measured by a stop-watch. The value 0.00893 dynes per sq. cm., as obtained by Hosking,¹ was assumed for the water which was used in standardizing the instruments.

² Kendall: J. Am. Chem. Soc., **42**, 1776 (1920).

viscosities of the pure components and x_1 and x_2 are their respective mole fractions) shows that the calculated values are too high on the average by 34%. As Kendall's equation has been found to give results within 0.7% of the experimental data in the case of the three alcohol mixtures previously studied, it may be considered as one of the properties of a perfect solution. On the basis of this test the present system is far from "perfect."

Summary and Conclusion

Reviewing the results of the various measurements, we find that

(1) A considerable heat absorption, amounting to 387 calories per mole in the case of the equimolal mixture, takes place on formation of the several solutions.

(2) An appreciable volume increase, on the average 0.3%, accompanies the process.

(3) The measured vapor pressures and partial pressures of the resulting liquids considerably exceed the ideal values calculated by means of Raoult's law.

(4) The observed viscosities for the various solutions exhibit on the average a negative deviation of 34% from Kendall's cube-root equation.

Judging the data as a whole, we are led to the conclusion that the system under discussion is far from "perfect." In this connection it is interesting to note that the combination of deviations from the behavior of a perfect solution—heat absorption and volume increase on mixing, together with a positive deviation from Raoult's law—is entirely consistent with the findings in studies on other systems.¹ For an explanation of the present results, we have re-

¹ Hildebrand: "Solubility," p. 63 (1924). We wish to take advantage of the present opportunity to express our appreciation of Professor Hildebrand's excellent monograph. In preparing this paper we have freely used the ideas expressed therein and are indebted particularly to Chapter VII, "Causes of Deviations from Raoult's Law."

course to the great differences in association factors and relative internal pressures of acetone and iso-propyl alcohol, as shown in Table I. These differences indicate that the molecules of iso-propyl alcohol have a much greater attraction for one another than for acetone molecules or than the acetone molecules have for each other. In the pure state, therefore, the iso-propyl alcohol molecules tend largely to associate, although such association is undoubtedly indefinite and not strictly stoichiometric. On the formation of solutions with acetone, these attractive forces in the iso-propyl alcohol are weakened and as a result there is a dissociation or break-up of the more or less indefinite associated groups or "group" molecules, accompanied by an absorption of heat and an increase in volume. This decreased association as far as the alcohol is concerned leads to its positive deviation from Raoult's law in the series of solutions; while on the other hand the inherent tendency of the alcohol molecules to associate, though weakened, produces a squeezing out effect on the acetone and positive deviations for this component also. The large negative deviations of the observed viscosities from Kendall's cube-root equation can also be attributed to the lessened forces of attraction and decreased association of the iso-propyl alcohol molecules in the various solutions.

THE STUDY OF THE TANNIN-GELATIN REACTION*

BY IMO P. BAUGHMAN

Purpose of Present Work

The purpose of this investigation was: (1) to devise a method for the quantitative determination of tannin in small amounts; (2) to study the tannin-gelatin reaction in the vicinity of the maximum flocculation point; and (3) to determine the effect produced by various electrolytes and by age on this reaction.

Part I

A Colorimetric Method for Tannin

Since tannin gives characteristic color reactions with various reagents under the proper conditions, and since the quantity to be estimated is small, the possibility of a colorimetric method was alluring. Sodium hydroxide was first used but found to be unsuccessful colorimetrically. The characteristic color produced by iron salts with tannin is in many respects ideal, but the difficulty is that many of the salts are so strongly colored that their excess masks to a certain extent the characteristic color sought. The use of ferrous ammonium sulfate seemed to offer a solution of the difficulty, and an extensive study of the method was made.

A sample tannin solution containing 0.0002 gm/cc was diluted still further by adding fifteen cc of distilled water, thus producing a solution containing 0.000125 gm/cc, and then an arbitrary amount of iron reagent was added. One portion was used as a standard, and to the other the iron reagent was added dropwise to test the effect of excess reagent. A set of readings was carefully taken after each addition. If the first two readings of each set were not the same, then three to five readings were taken, and the average obtained. The accompanying graph, Fig. 1, in which readings in mm are plotted against increasing amounts of iron reagent added to a constant quantity of tannin, shows that a maximum reading is obtained beyond which an excess of the iron reagent causes no change in color.

A solution of tannin containing 0.00033 gm/cc was diluted to one-half, one-third, and one-fourth that concentration, and the resulting solutions tested as follows, the Kober type of colorimeter being used throughout this work. Table I gives the observed and calculated values in tabular form. In the column under the heading "Tannin, gm/cc," are given the amounts of tannin present in each sample as determined by dilution from the known solution. In the next column under Readings are recorded in mm the actual values obtained from the colorimeter for the samples as indicated. In the next column are given the values calculated from the preceding column. Thus

*This article is abstracted from the thesis submitted to the Department of Chemistry of the Leland Stanford Junior University in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

in sample number one the more dilute solution was set at a reading of 60.0 mm. The other cup should have given a reading of 30.0 mm since the solution it contained was twice as strong as the first. Or assuming that 29.7 mm was correct then the other reading should have been twice that or 59.4 mm. Then from the actual readings taken the amount of tannin present was calculated and recorded in the last column: taking the readings 60.0 and 29.7 mm and the 0.00033 gm/cc sample as standard, then,

$$0.00033 : x :: 60.0 : 29.7$$

$$x = 0.000163$$

On the other hand, using the 0.000166 gm/cc sample as standard,

$$0.000166 : x :: 29.7 : 60.0$$

$$x = 0.000335$$

FIG. 1

TABLE I

Actual		Calculated	
Tannin gm/cc	Readings mm	Readings mm	Tannin gm/cc
1. 0.000330	29.7	30.0	0.000335
0.000166	60.0	59.4	0.000163
2. 0.000330	19.9	20.0	0.000334
0.000111	60.0	59.7	0.000109
3. 0.000330	19.9	20.0	0.000333
0.000083	80.0	79.6	0.000082
4. 0.000330	30.1	30.0	0.000331
0.000166	60.0	60.2	0.000166
5. 0.000330	19.8	20.0	0.000335
0.000166	40.0	39.6	0.000163
6. 0.000330	19.8	20.0	0.000333
0.000111	60.0	59.4	0.000109
7. 0.000330	20.1	20.0	0.000330
0.000083	80.0	80.4	0.000083

Thus it is seen that the characteristic blue color is produced by the action of ferrous ammonium sulfate on a solution of tannin with an intensity of color which increases proportionally to the concentration of tannin, provided an excess of the iron reagent is present sufficient to react completely with all the tannin. The readings in mm, when the solutions are compared in the colorimeter, vary inversely as the concentration of tannin in the sample.

This method has been worked repeatedly for rapidity and accuracy. As a result of much experience with the method the following set of directions has been devised and found satisfactory. The iron reagent is prepared by making a saturated solution of ferrous ammonium sulfate. This solution is filtered and the resulting clear filtrate used as a stock solution. One cc of this reagent is used for a 10 cc sample of tannin solution containing not more than 0.0002 gm/cc. A concentration of tannin greater than this cannot well be used since it produces too dark a color.

Besides the iron reagent it is also necessary to have a standard solution of tannin of known concentration not to exceed 0.0002 gm/cc to which the unknown can be compared. The tannin used for solution in these experiments was Kahlbaum's purest product. Ten cc of the standard tannin solution are measured into a test tube; then a measured volume of the solution containing tannin in unknown concentration is diluted to a total volume of 10 cc (a preliminary test having previously been made to determine approximately the intensity of color); 1 cc of the iron reagent is added to each, and the two compared colorimetrically.

Experimental. Part II

Preparation and Preservation of Dilute Tannin and Gelatin Solutions for Long Periods.—One-half per cent solutions of tannin were prepared in the following manner: 5 gms. of tannin were dissolved in 1000 cc of water, boiled one-half hour, cooled, diluted to 1000 cc, poured into tall cylinders, and allowed to stand until settling was complete. Several hours later the liquid was poured into a 1000 cc glass-stoppered reagent bottle. Any very small particles still remaining soon settled and the clear supernatant liquid was drawn off by means of a pipette and diluted as desired. The bottles used for storage must be thoroughly clean and free from foreign matter, otherwise mold is liable to appear within a few days. It is an interesting fact that mold so produced is present in a concentric ring formation.

The gelatin used for the solutions in these experiments was the ordinary variety of Knox gelatin, several packages being obtained and the contents thoroughly mixed to assure as uniform material as possible. A sterile 0.5 per cent solution was prepared in the following manner: 5 gms. of gelatin were allowed to stand in 200 cc of distilled water for about 20 minutes. Then the mixture was heated until all the particles were dissolved. This was then diluted to 1 liter and the liquid introduced into a flask of one and a half liter capacity fitted with a two-hole rubber stopper, carrying in one hole a piece of glass tubing penetrating nearly to the bottom of the solution and above the stopper, which was bent like a siphon and closed at the end by a rubber tip and screw clamp; in the other hole was placed a straight calcium chloride tube so packed with absorbant cotton that air could just be forced through. The solution was heated in the flask until steam passed through the cotton, the contents being thus sterilized. Portions of the solution were obtained by opening the screw clamp and blowing through the calcium chloride tube.

This method of preparing and keeping the gelatin solutions was used very successfully. Solutions have been kept over three years and still show no evidence of mold.

The Flocculation Point of Tannin and Gelatin Solutions.—Wood¹ in working with tannin and gelatin found the greater quantity of gelatin-tannin precipitate obtained if about six times as much tannin as gelatin (in two per cent solution) was present. In 1910 Trunkel² reported that mutual flocculation of gelatin-tannin solutions occurs; that a point can be reached at which gelatin and tannin are both completely flocculated; and that a freshly prepared gelatin solution requires more tannin than does a twenty-four hour old gelatin solution. Thomas and Frieden report that gelatin is completely precipitated by gallotannic acid when the ratio of tannin to gelatin is not less than 2:1, and the gelatin-tannin precipitate is not soluble in excess of tannic acid; and that the ageing of gelatin solutions has no effect on the sensitivity in testing for tannin, provided bacterial action is prevented. For further literature on the Tannin-Gelatin Reaction see Thomas and Frieden.³

In order to determine approximately the point of maximum flocculation for tannin and gelatin solutions a set of preliminary tests was made by preparing several series of 10 cc samples of the two solutions in varying concentrations and mixing them. Since in many cases the order of addition of colloids makes a difference in their action, any possible complication from this cause was avoided by observing a definite order throughout the experiments. Each set consisted of 9 samples made up in the following way: into the first test tube was introduced 1 cc of a one-half per cent gelatin solution using a 10 cc pipette graduated in tenths; into the second, 2 cc; the third, 3 cc; and each tube in like manner up to and including the ninth. To number one was added 9 cc of a one-half per cent tannin solution; to tube number two, 8 cc of tannin; to number three, 7 cc; each tube in order being treated similarly until at the end there were nine tubes each containing 10 cc of a mixture of one-half per cent gelatin and one-half per cent tannin solutions. Each tube was inverted once only to mix thoroughly the contents and then restored to its original upright position. Flocculation occurred in each case as soon as the two solutions came into contact. After the precipitates had settled, the first five samples usually showed a clear supernatant liquid; samples six and seven were quite milky and frequently eight and nine were less milky than the preceding two. The samples were allowed to stand a few hours in order that the precipitates might settle to a certain extent, and then each sample was filtered by means of a heavy asbestos pad in a Gooch crucible.

The filtrates only were used in all cases, the precipitates being discarded. Ordinarily the first half of the series gave clear filtrates, but the following ones were milky in appearance and varying in degree from one series to another.

¹ Dekker: "Die Gerbstoffe" p. 321.

² Biochem. Z., 26, 458-493 (1910).

³ J. Ind. Eng. Chem., 15, 841 (1923).

The samples giving milky filtrates were also very difficult to filter. The filtrates were tested qualitatively for tannin and gelatin, the sodium hydroxide and picric acid tests being used respectively.

Table II gives typical results obtained from testing several series for the presence of tannin and gelatin.

TABLE II

	tannin present		gelatin absent	
1.	"	"	"	"
2.	"	"	"	"
3.	"	"	"	"
4.	"	"	"	"

The quantities and concentration were happily chosen, as the apparent point of maximum flocculation is about at the middle of the series. Hence for all subsequent work the same concentration of solutions was used and the quantities made up in like series as indicated above. In order to follow the conduct of tannin-gelatin reactions many series of samples were prepared and the filtrates tested not only qualitatively for the presence of tannin and gelatin but also quantitatively for the amount of tannin using the colorimetric method devised.

Quantitative Study of the Tannin-Gelatin Reaction.—The colorimetric method described in Part I for the determination of tannin in small amounts was now used in studying the tannin-gelatin reaction. The method here was identical with that used in the preliminary qualitative work, except that the tannin in the filtrates was determined quantitatively by means of the colorimetric method described in Part I. Table III shows the analysis of the filtrates from four series of samples. The sample number is the same as the number of cc of gelatin in that particular sample and the total volume of each sample is 10 cc. In the "Ratio" column are given the ratios of tannin found in the filtrate to the tannin originally present in the sample.

From a study of these results it is seen that when tannin and gelatin are mutually flocculated, there is a point of maximum flocculation beyond which with increasing gelatin some flocculation still occurs, but a decided protective action also comes into play. The largest amount of tannin found in the filtrate is from 27 to 30 per cent of the original quantity in sample number one. The quantity decreases rapidly in the following samples to number five at which point the smallest amount of tannin is found—about 10 per cent of the original quantity. In samples six to nine inclusive the tannin content of the filtrates increases though not quite so rapidly as it decreased at the beginning of the series, about 25 per cent of the original amount remaining in the ninth sample.

The Effect of Electrolytes on Tannin-Gelatin Reactions.—The effect on tannin-gelatin reactions of electrolytes in varying concentrations was observed in the following way: a 6 per cent solution of the electrolyte was prepared, and 2 cc of this solution added to every test tube in the series of 18 samples, making in each tube a total volume of 12 cc of tannin and gelatin in varying proportions but always with a 1 per cent solution of the electrolyte present. Later a 12 per cent solution of the electrolyte was prepared, which when added to the two sets of a second series of 10 cc samples in portions of 2 cc gave a salt concentration of 2 per cent; and finally a 24 per cent solution of the electrolyte was used giving the effect of 4 per cent salt present in the dilution used. The electrolytes were chosen particularly with respect to the anions and cations to see if there was any noticeable difference in their action. Certain salts could not be used on account of interference in various ways with the necessary colorimetric tests. Barium salts had to be eliminated on account of the precipitate formed with ferrous ammonium sulfate and colored salts also could not be used on account of interference with the characteristic color of the iron tannate to be formed. The results of duplicate sets are given in Tables IV-XIII.

The results show that one per cent sodium chloride appreciably reduces the amount of tannin in the filtrate, while all other salts appreciably increase this amount.

The Effect of Age of Gelatin Solutions.—To find the influence of the age of a gelatin solution upon flocculation, the same tannin solution was used with gelatin solutions of different age. Sets were prepared and analyzed just as in the preceding work. The solution of gelatin used in set number one was twelve months old, and the solution used for set number two was twelve hours old. As they formed, the precipitates in the case of set number two seemed to be much heavier and whiter than those in set number one, but at the end of a few hours the two sets had much the same appearance. The precipitates were removed by filtration with Gooch crucibles and suction. Tables XIV-XV show the results.

Ten days later the two same gelatin solutions were used for another series of tests:

TABLE XV

Sample Number	Tannin gm/cc	Tannin gm/cc	Ratio	Tannin gm/cc	Ratio
	Original	Final		Final	
1.	0.00450	0.00155	.344	0.00186	.414
2.	0.00400	0.00132	.330	0.00150	.375
3.	0.00350	0.00114	.326	0.00114	.326
4.	0.00300	0.00055	.183	0.00058	.193
5.	0.00250	0.00033	.132	0.00031	.124
6.	0.00200	0.00028	.140	0.00028	.140
7.	0.00150	0.00028	.186	0.00027	.180
8.	0.00100	0.00025	.250	0.000296	.296
9.	0.00050	0.00024	.480	0.00028	.560

These results show that age has no effect on the tannin-gelatin reaction when sterilized gelatin solutions are used. This is in accord with the findings of Thomas and Frieden.¹

Summary and Conclusions

1. Ferrous ammonium sulfate can be used to determine tannin colorimetrically in small amounts, the method being sensitive to ± 0.000005 gram per cc of tannin.
2. There is a point of maximum flocculation for one-half per cent strength tannin and gelatin solutions and beyond this point the protective action of an excess of gelatin on tannin is marked.
3. Gelatin is completely precipitated by tannin.
4. Some tannin remains in solution in all cases.
5. The highest percentage of tannin present in a one-half per cent solution is flocculated by an equal volume of a one-half per cent gelatin solution.
6. One per cent sodium chloride causes considerable decrease in the amount of tannin remaining in the filtrate.
7. The age of a sterilized gelatin solution does not affect flocculation by tannin.

Acknowledgment

This investigation was carried out in the Physical Chemistry Laboratory at Stanford University at the suggestion and under the direction of Professor S. W. Young. Acknowledgment is made for the helpful suggestions and advice of Professor Young throughout the work.

THE SOLUBILITIES AND DENSITIES OF SATURATED SOLUTIONS OF SODIUM AND POTASSIUM HALIDES AT 25°

BY ARTHUR F. SCOTT AND W. RONALD FRAZIER

In order to compute "The Changes in Volume upon Solution in Water of the Halogen Salts of the Alkali Metals," Professor G. P. Baxter¹ and his students have made an elaborate series of measurements of the densities of these solutions over a wide range of concentrations for temperatures between 0° and 100°. Only in a few cases, however, were measurements made with saturated solutions. It was the original intention of the present investigation to fill in this gap and further, to make a systematic series of solubility determinations over the same range of temperature. This work, unfortunately, has been interrupted and its completion must be postponed indefinitely; consequently, it seems desirable to publish the results which have been obtained up to the present time.

Purification of Materials

Throughout the present investigation the earlier work was taken as a model and every effort was made to attain the same degree of precision in order that the two sets of data would be on a comparable basis. Accordingly the preparation and purification of the materials used followed as nearly as possible the methods described in the second of the papers already cited. The few cases where this duplication was not possible, are noted below:

Sodium bromide and *sodium iodide* were obtained by treating recrystallized sodium carbonate with purified hydrobromic and hydriodic acids respectively. The products thus obtained were then crystallized twice in a quartz dish, and in both cases the salts were dried in an electrically heated porcelain furnace at 300° for four hours.

Silver nitrate was purified by making a saturated solution of analytically pure material which was then precipitated by the addition of an equal volume of redistilled nitric acid. The crystals were separated from the mother liquor by means of centrifuging. When dry, they were brought just to the fusion point. The solutions of this salt which were employed in the solubility determinations, were prepared immediately before they were used.

Apparatus

The Thermostat.—The solutions used in the density and solubility measurements were brought to the saturation state in a constant temperature bath. The temperature of the bath was controlled by a large, four-finger mercury-toluene regulator and was readily kept constant to within 0.01°. When in operation, the bath was maintained at 25°, the temperature being determined by a fifty-degree thermometer calibrated by the Bureau of Stand-

¹ Baxter, Boylston, Mueller, Black, and Goode: J. Am. Chem. Soc., 23, 901 (1911); Baxter and Wallace: 38, 70 (1916).

ards. This thermometer was graduated in tenths of a degree and could be read to hundredths. In the thermostat was also a contrivance for rotating the flasks containing the solutions to be saturated. This part of the apparatus was completely immersed in the bath.

The Flasks.—Density measurements were made by means of two ordinary 25 cc. graduated flasks, the necks of which had been constricted to secure greater accuracy in setting the meniscus. The interior diameter of the constricted portion of the neck was 2-3 mm. The volumes of the two flasks were determined by finding their water content at 25°. To accomplish this the flask was allowed to remain in the constant temperature bath until the meniscus attained a constant position, which operation usually required two to three hours. Finally the meniscus was adjusted and the neck of the flask was dried by touching it with a piece of filter paper. The flask was always weighed with a similarly treated counterpoise and both were allowed to stand in the balance case one hour before weighing. From the apparent weights of water the volumes were calculated by multiplying by the factor, 1.004001, the density of water at 25° being assumed to be 0.997071. These figures are taken directly from the paper by Baxter and Wallace. The flasks were calibrated at the beginning and at the end of the work which lasted over a period of three months. The apparent weights of the water in both cases showed a change of only 0.1 mg.; hence the volumes may be assumed to have remained constant.

Procedure

The solution to be saturated was contained in a 250 cc. bottle, the ground glass stopper of which was carefully fitted. Usually about 80 cc. of solution was made so that there would be present approximately 5 gm. of the solid salt at saturation. Particular care was taken in sealing the flask. The neck of the bottle was always completely dried before the stopper was inserted. Then the stopper was coated with paraffin and finally wired to the neck of the flask. It was found that this precaution prevented contamination from the bath and also kept the mouth of the bottle dry for subsequent operations. The bottle containing the solution was next placed in the rotating device in the thermostat and shaken for one hour, after which it was allowed to stand in the bath for one hour. With the exception of the iodides these two operations were repeated several times before the solution was used, although tests demonstrated that this repetition was superfluous.

Several methods of transferring the saturated solution to the density flask were tried and the following, which was the one finally adopted, was undoubtedly just as accurate as the others and had the advantage of being the simplest. When the solution was ready to be transferred, the bottle was held in the bath so that only the neck protruded. The glass stopper was carefully removed and replaced by a two-hole rubber stopper. In one hole of the stopper was one arm of a small, inverted glass U-tube, the bend coming just above the stopper. The arm of the tube in the saturation bottle extended almost to the bottom; its end was sealed off and a small hole was blown in the side of the tube about 1 cm. from the end. This was done in order to prevent

any crystals on the bottom of the bottle from being carried over into the density flask. The other end was drawn into a fine capillary which fitted into the constricted neck of the density flask. The second hole of the rubber stopper was provided with a small piece of glass tubing through which a slight pressure could be exerted, thereby forcing the saturated solution over into the density flask. Of course the density flask and also the transferring tube were kept in the constant temperature bath previous to use.

After the transference of the saturated solution in the above manner, the density flask was allowed to remain in the bath for about half an hour. Then the flask along with some of the water was removed from the thermostat in a Dewar beaker. This Dewar beaker was transparent and slightly larger than the density flasks. With the flask thus in the beaker it was a comparatively easy matter to set the meniscus by means of small capillary tubes, an operation which required usually about a minute. Following the preliminary adjustment of the meniscus the density flask was again set in the thermostat for fifteen minutes and the meniscus was checked in the same way. When the adjustment had been found satisfactory, the neck of the flask above the constriction was wiped with a small piece of filter paper. Measurements made with a Beckmann thermometer showed that the temperature of the water in the Dewar beaker changed only 0.006° in three minutes, a variation which was less than that of the bath itself.

To correct the weight of solution to vacuum, it would have been necessary to know the exact volume at the temperature of weighing. Since this was not easy to ascertain, it was assumed that the volume was the same as at 25° . This assumption would not introduce any great error because the temperature at the time of weighing was never far from that of the bath. In all cases, therefore, the weights of solutions were corrected to vacuum by the usual formula involving terms for barometric and vapor pressures.

That the above procedure for obtaining a saturated solution and then its density is rather satisfactory, can be seen in the results of solutions of sodium chloride. In this case four different solutions prepared on four different days exhibited an extreme difference in density values of only one part in fifteen thousand.

Usually only one solution was prepared. After portions had been transferred to the two density flasks, two samples (approximately 5 cc.) were transferred to each of two tared weighing bottles. A second weighing gave, of course, the weight of the sample. These samples were next transferred carefully to one liter, glass-stoppered Erlenmeyer flasks, and diluted to about 500 cc. From the weight of the solution the weight of silver nitrate necessary to precipitate the halogen content was computed. This quantity plus an excess of about 0.5 gm. was dissolved in 150 cc. water. Then, after the salt solution had been made acid by the addition of 1 cc. of concentrated nitric acid, the silver solution was added slowly with constant stirring. The mixture was shaken and the precipitate permitted to settle over night. The precipitates obtained in this manner were next washed in order to eliminate the alkali nitrate present. In the case of the bromide and iodide precipitates the

washing was done by decantation, five times with pure water; in the case of the more soluble chloride precipitate, however, the washing was also by decantation, but first with a one percent silver nitrate solution and finally once with pure water. Following the washing the precipitates were transferred to Gooch crucibles and heated in an oven at 120° to constant weight.

Results

The data obtained in the present series of measurements are tabulated in Table I.

TABLE I
Density and Solubility Data

Salt	Weight of solution in vacuum	Volume of solution	Density	Vacuum weight of sample	Vacuum weight of AgX	Weight of salt in sample	Grams salt in 100 grams water

It should be noted that the data for the iodides are less certain than those for the other salts. This is due to the fact that the saturated solutions appeared to liberate iodine on standing. For this reason the solutions were used as soon as possible after preparation.

It is of interest to compare the results presented in this paper with those given in the literature. Apparently the only density values available are those determined by Berkeley.¹ His figures for 25°, obtained by interpolation, are given below:

¹ Berkeley: Phil. Trans., 203 A, 189 (1904).

	Berkeley	S and F
NaCl	1.1978	1.19796
KCl	1.1779	1.17786

In the paper of Baxter and Wallace curves are given which show the variation of the contraction in volume per gram of salt with a change of concentration. If the contraction for a saturation solution is computed in the same way, their representative points, when plotted on the above graph, fall precisely on extensions of the proper curves. Such a figure is not presented here because of the incomplete nature of this paper.

Summary

The present communication gives values for the densities and solubilities of saturated solutions of the chlorides, bromides, and iodides of sodium and potassium at 25°.

All of the measurements recorded in this paper were made at Reed College while most of the material was prepared at Harvard University. The authors wish to acknowledge the kindness of Professor Baxter in permitting one of us to work in his laboratory during the summer of 1924. A grant from the du-Pont Fund at that time helped to defray part of the expense of the materials.

THE IMBIBITION OF GELATIN DRIED AS A GEL AND AS A SOL*

BY ROSS AIKEN GORTNER AND WALTER F. HOFFMAN**

In an earlier paper¹ we have shown that the rate of imbibition and the extent of the imbibition of gelatin particles immersed in water is to a considerable extent dependent upon the previous treatment of the gelatin, *viz.* the concentration of the gelatin gel before drying. A gelatin prepared from a 5 per cent gel would swell faster and imbibe more water, reaching a different apparent equilibrium with water, than would a gelatin preparation dried from a 15 per cent gel.

From these experiments the conclusion was drawn that gelatin gels possessed a structure which persisted throughout the drying process and that this structure limited the volume of water which the dried particles could reimbibe. Sheppard and Elliott² report similar results but attribute the difference in rate of swelling to "case hardening" or surface drying effects. Our experiments, where uniform sized particles were employed, would appear to exclude differences due to surface drying changes.

The experiments described below were carried out to ascertain, if possible, whether gelatin of different concentrations, dried both as a sol and as a gel, would imbibe water at the same rate and to the same extent. It was also hoped that these experiments might throw some light upon the question as to whether the so-called sol and gel forms of gelatin actually exist as physical entities.

The gelatin sols and gels were prepared as follows. The gelatin³ was soaked in warm water for about 30 minutes and then heated slightly in a water bath until it was an apparently uniform sol. Equal volumes of the gelatin sols were then poured into tin pie plates, and dried. Those dried as a "gel" were allowed to become rigid and then dried in a current of air at a temperature below the "melting" point. Those dried as a "sol" were placed in an electric oven and dried at 45°C. When dry, the sheets from both the sols and gels were broken into small pieces and dried for several days at 45° in an electric oven. They were then stored for use in a desiccator over calcium chloride.

For determining the rate and extent of imbibition the same technic as was used previously, was employed. About 2 gms. of the gelatin were placed in a tared Gooch crucible and the crucible was then set in a beaker of distilled water for a definite time. The crucible was then removed from the water and

³ The gelatin was from the same sample used in the previous study. The percentage of the gel was calculated on the basis of the air-dry gelatin, *e. g.*, a 10 percent gel means 10 grams of the air-dried gelatin plus 90 grams of water.

whirled in a centrifuge for a short time at low speed in order to remove the excess water in the crucible. The crucible and contents were then weighed and the amount of imbibed water calculated. After weighing, the crucible was again placed in the water for a definite period and again weighed in the same manner.

The results of the first series of experiments are given in Table I.

TABLE I

The Imbibition of Particles of Gelatin dried as a "Gel" and as a "Sol"

Source of Gelatin Particles			Grams water imbibed per gram dry gelatin*

10% " "	5.33	7.03	8.21	9.00	10.28	11.38	13.71	14.63
15% " "	5.32	6.70	7.59	8.48	9.12	10.52	12.10	13.35
20% " "	4.19	5.88	6.84	7.45	8.50	9.88	12.06	12.96

*Average of duplicate determinations. In this experiment the gelatin was ground to pass a 2 mm. mesh and was all retained on a 1 mm. mesh.

In the above experiment no careful attempt was made to control the size of the fragments of gelatin which were placed in the crucible. Accordingly the experiment was repeated, using dried gelatin which had been broken up

in a mortar and sieved so as to secure particles which would pass a 2 mm. sieve and be retained upon a 1 mm. sieve. The results of the experiments, using such particles, are shown in Table II. In our opinion these results are more trustworthy than are those of Table I, because of the added feature of controlled particle size.

The results where gelatin gels were employed are in general agreement with our earlier experiments. However, it is somewhat difficult to completely reconcile our earlier theory with the results which we have obtained with the gelatin sols, for with the "sol" gelatins there is also to be observed an effect of the original concentration of the sol from which the gelatin was prepared.

Certain rather striking differences between the sol and gel preparations are evident:

1. The particles from the 2.5 per cent gelatin sol (Table I) began to solate after 6 hours, whereas similar particles prepared from a 5 per cent gelatin gel showed no sign of solation at the end of 24 hours.
2. While in some instances the initial rate of imbibition appears to be higher in the case of the gelatins prepared from the sols, in every instance the amount of water imbibed at the expiration of 12, 24 and 48 hours is greater in those gelatins dried down as gels.
3. The preparations from 10 per cent, 15 per cent, and 20 per cent sols show very similar values when the particle size is controlled (Table II), whereas similar preparations from the gels show a decided progressive decrease in their imbibition rate.
4. The cause of the striking differences between the preparations from a 5 per cent sol and a 10 per cent sol (Table II) cannot be explained from the available data.
5. It will be noted that the preparation from the 5 per cent sol had a greater imbibition rate during the first six hours, but that the values for 8, 12, and 24 hours are lower than are those for the preparation from the 5 per cent gel.

It is evident from the above data that dried gelatin preparations reflect in a very considerable measure their previous history. No one theory appears to be adequate to explain this behavior, but it is our belief that the contrast between the behavior of the sol and gel preparations is at least in part due to the presence of a persistent gel structure.

It may well be that during the process of drying, the gelatin sols developed a more or less fixed structure which is reflected in the subsequent swelling curves. The existence in the dry state of a sol form which is distinct from a gel form of gelatin is neither proven nor disproven by these experiments.

NEW BOOKS

Colloid Symposium Monograph. Edited by H. B. Weiser. Vol. I V. 23 × 16cm; pp. 378. New York: Chemical Catalog Company, 1926. Price: \$6.50. Mr. Weiser has done very good work in getting out so promptly the papers presented at the Fourth Colloid Symposium. The papers and authors are: A Survey of the Main Principles of Colloid Science, by J. W. McBain, pp. 7-18; The Colloid Particle as revealed by Catalytic Studies, by H. S. Taylor, pp. 19-28; The Water Equilibrium, by W. D. Bancroft, pp. 29-37; Making and breaking Emulsions, by W. P. Davey, pp. 38-43; Emulsification—a Study of Oil-soluble Emulsifying Agents, by Brian Mead and J. T. McCoy, pp. 44-57; The Mechanism of Adsorption and of the Swelling of Gels, by Charles Terzaghi, pp. 58-78; Specific Ion Effects in the Behavior of Tanning Agents toward Collagen treated with Neutral Salts, by K. H. Gustavson, pp. 79-101; Observations of the Colloidal Behavior of Aqueous Gelatin Systems, by E. O. Kraemer, pp. 102-121; Mass Action Effects in the Interaction of Gelatin and Acids, by W. K. Lewis and C. T. Daniell, pp. 122-131; The Helmholtz Double Layer related to Ions and Charged Particles, by E. F. Burton, pp. 132-144; X-rays and Colloids, by G. L. Clark, pp. 145-173; The Structure of Ramie Cellulose as derived from X-ray Data, by W. H. Dore and Sponsler, pp. 174-202; Organophilic Colloids, by G. S. Whitby, pp. 203-223; Colloidal Properties of the Surface of the Living Cell, by J. F. McClendon, pp. 224-233. The Function of Carbon Membranes in Osmosis, by F. E. Bartell and J. J. Osterhof, pp. 234-245; Electro-endosmosis through Wood Membranes, by A. J. Stamm, pp. 246-257; The Place of Adhesion in the Gluing of Wood, by F. L. Browné and T. R. Traux, pp. 258-269; Methods for Cutting and Differential Staining of Microscopic Sections of Hardwood Glue-Joints, by A. I. Weinstein, pp. 270-280; Flocculation and Deflocculation of the Silver Halides, by S. E. Sheppard and R. H. Lambert, pp. 281-301; Pectin Jellies, by Miss G. Spencer, pp. 302-303; Cataphoresis, Electrical Charge, Critical Potential, and Stability of Colloids, by H. R. Kruyt, A. C. W. Roodvoets and P. C. van der Willigen pp. 304-310; The De-inking of Paper, by T. R. Briggs and F. H. Rhodes, pp. 311-327; The So-called Adsorption of Ferric Oxide Hydrosol by Charcoal, by A. W. Thomas and T. R. LeCompte, pp. 328-353; Ionic Antagonism in Colloid Systems, by H. B. Weiser, pp. 354-373.

It is rather a surprisingly good collection of papers and it will take some work to get together a better selection for the Fifth Colloid Symposium which is to be held at the University of Michigan in June, 1927. These meetings have been so successful that it has been thought wise to organize a Colloid Division of the American Chemical Society, under whose charge the next meeting will be held. This is as it should be. The need for these meetings has been shown and it is very desirable to have all successful efforts in chemistry at least officially part of the work of the American Chemical Society. The monographs will undoubtedly sell better when published under the auspices of the American Chemical Society, so both parties will profit by the arrangement. The Division of Chemistry of the National Research Council can now go ahead and develop some other field of activity—perhaps photochemistry.

It may be of interest to quote some passages from this volume to show how interesting it is and of what value it should be to the chemist.

"The two main problems of colloid science are structure and stability. What is the structure which places matter in this category? Whence do such structures derive such a measure of stability as to constitute nearly all the common materials met with in daily life? The answer to the first question is definitely that in most cases the unit of which colloids are built up is not the mere molecule but a higher organized unit, the particle called by Nägeli the micelle.

"The question of stability has not been properly faced. I submit that there is a class of substances whose most stable state is the colloidal condition. They are thermodynamically stable in the strictest sense, in that the colloid state is for them more stable than the crystalline or crystalloidal. Many substances have never even been brought into the

crystalloidal state, so that proof is necessarily lacking just because they are too strongly colloidal. Nevertheless there are some intermediate substances where both the colloidal and crystalloidal states are producible at will, because they are almost equally stable. This is the most important result of the study of soaps. Here we can have perfect true crystals in true reversible equilibrium with a solution in which soap exists partly as colloid and partly as crystalloid. From the standpoint of the strictest thermodynamic criteria they possess an exactly equal degree of stability. Under other conditions the colloid form is more stable and the crystal or the true crystalloidal solution passes spontaneously into the colloidal form, thereby demonstrating the lower free energy of the colloidal state for such cases. We have shown that the phase rule governs the external equilibria of all such phases.

"It is evident that this point of view embraces not only sols but also jellies and gels. If accepted, it is much more heartening than the conception, hitherto universal, that colloids are inherently unstable formations which have been brought by various devices into this state of dispersion and are rather precariously kept there, either on account of slow rate of reaction or through a balance of compensating factors which inhibit alteration," p. 7.

"In dealing with the proposed class of thermodynamically stable colloids, I would further suggest that they can only then be truly stable when the micelle has such a structure that part of every molecule of the micelle is exposed to the solvent. This idea can be best developed by illustration. For example if water and palmitic acid are sealed up in an evacuated tube the most stable and therefore permanent state is that where the palmitic acid forms a monomolecular film upon the surface of the water, any excess remaining as a crystal or crystals," p. 8.

"The Donnan distribution law appears to be of universal validity for all solutions containing electrolytes. That is, within all parts of a system in equilibrium, for example, within any colloidal solution, or within the different parts of a jelly, the product of the activities of every pair of monovalent diffusible ions must be constant. Approximately, the ionic product in terms of concentration should be constant throughout. Any change subject to a spatial constraint will cause a correspondingly redistribution of all other ions in the neighborhood, but the ionic product for each pair of free ions is constant. There is no need of a membrane, as Procter and especially Wilson have shown, to produce the constraint, although the distribution may be highly local and the constancy merely statistical.

"While therefore the Donnan distribution occurs wherever several diffusible ions are present, there is serious doubt about the numerical value of the so-called osmotic pressures (really differential pressures against solution of electrolytes) which have been obtained with colloids so far. The experimental values range from one half to tenfold those predicted. Some doubt also attaches to the "membrane potentials" because the diffusion potentials between solutions of potassium chloride and those containing a nondiffusing colloid ion have not yet been elucidated, so that opinions differ.

"Grossly exaggerated claims have been made by Loeb and others as to the part the Donnan equilibrium plays in colloidal behavior. Loeb's *ad hoc* definition would exclude most of the phenomena of colloids from that subject. For example the fact of gelatination or of coagulation was referred to the subject of "solubility," not of "colloidal behavior." Even in the effects he observed (his experimental results of course are not here in question) the Donnan distribution is only a factor. Two of the three or four phenomena he studied were effects of electrolytes on swelling and on viscosity. In both fields there are other instances of effects on swelling and on viscosity which exceed his tenfold in magnitude and yet cannot be ascribed to the Donnan equilibrium. For example in the case of soaps, so closely related to Loeb's materials, when the viscosity is increased fifty-fold by addition of salt the effect is comparatively enormous and it is in the opposite direction to that predicted by Loeb for salts. The other aspect of Loeb's work, which has been most useful, is his emphasis upon the predominant importance of hydrogen and hydroxyl ions. Few would care to deny chemical action between acids or bases and amino acids or their protein derivatives, but the quantitative formulation is that of sorption, and other investigators have shown that sorption of various ions is not negligible.

"The effects of Hofmeister or lyotrope (Freundlich) series of ions are too striking to be ignored. They have been observed with too many types of colloids and in connection with too many systems not even containing colloids to be attributed to systematic experimental error (Loeb). Many of the salient phenomena of reversible colloids such as coagulation by heat are profoundly affected, and often in different directions in acid and alkaline solutions. Similarly with the coagulation of reversible colloids by electrolytes, or their gelatination, or the swelling of jellies. A remarkable case in point is afforded by Michaelis' observations on the swelling of konyaku in various electrolytes. Recent workers who have fulfilled Loeb's injunction to keep the pH of their solutions constant have nevertheless observed these effects and found that sorption of these ions occurs and is specific," p. 15.

"It is significant that, in the case of formic acid decomposition, in presence of metal catalysts the reaction products are exclusively those of dehydrogenation, hydrogen and carbon dioxide, irrespective of the metal. With oxide catalysts, on the other hand, the products may be dehydrogenation as, for example, with zinc oxide, or mainly dehydration as, for example, with aluminium oxide. To what can this variation be attributed? A metal surface is composed of metal ions and electrons, an oxide surface of metal ions and oxide ions. The conclusion seems inevitable that, on the metal ion (positively charged) the dehydrogenation process occurs, whilst on the oxide ion, dehydration occurs. Attachment to the positive ion has the effect of giving the hydrogen atoms in the formic acid molecule greater freedom, in agreement with the observation made above that substitution by an electronegative substituent such as chlorine causes the hydrogen ion to have greater freedom. The negative ion causes the hydrogen atoms to be more firmly attached and so the dehydration split is favored. On this basis, an oxide catalyst surface is to be regarded as composed, not of a single catalyst, but of two catalysts, metal ions and oxide ions and the nature of the changes induced in the adsorbed reactant is determined by the charge of the ion on which the reactant molecule is adsorbed. The extent of the two alternative changes will be determined by the relative extent of adsorption of reactant on the two ions, on the relative frequency of the two ions in the surface and on their specific individual catalytic activities. These several factors, extent of adsorption, frequency of ions in the surface and catalytic activity will be determined by the degree of saturation of the lattice ions (i. e. catalyst structure) and by the extent to which the ions are already covered by poisons (salts, ammonia, water, etc.). This conclusion is in good accord with the data of colloid chemistry. It is of inestimable advantage in catalytic study since it permits a forecast of catalytic phenomena," p. 25.

"Attention is called to the fact that Procter's mass action equation for the reaction of gelatin in acid implies either that the molecular weight of gelatin is not greater than double its equivalent weight, or else that all the amino groups in gelatin have the same acid strength. It is also shown that this equation breaks down completely in the face of Loeb's data obtained at low hydrogen ion concentrations. It is demonstrated that isoelectric gelatin acts as a weaker base than gelatin which has already combined with some acid. It is further pointed out that this behavior can be quantitatively explained on the assumption of internal interaction of amino groups and carboxyl groups in the gelatin itself. A general mass action expression for the interaction of gelatin and acid is derived, including a correction term for internal compensation of the basic and acidic groups of gelatin in the neighborhood of the isoelectric point. Qualitative implications of this internal compensation's effect on the viscosity of gelatin solutions are discussed," p. 131.

"Of the various glucose formulae that come into consideration as possible structural units of cellulose, we may immediately reject the open chain aldehydic structure, since cellulose fibers normally show negligible aldehydic reactions, and consequently cannot be made up of units which contain active aldehyde groups. The possibility would remain that the structural units are straight chain, non-ring units in which the potentially aldehydic carbon atom is linked by an oxygen bridge to a carbon atom in another similar glucose unit, as in the constitutional formula proposed by Schorger.

This conception must also be rejected, however, since the C-O-C linkage would require a rectangular spacing of 2.75 Ångstrom units between chains, calculated from the sum of the atomic radii involved, whereas the X-ray data indicate definitely that the spacing between chains is 6.10 Ångstrom units in one direction and 5.40 in the other. Further grounds for the rejection of both straight chain formulae are found in the fact that a chain of six carbon atoms when fully extended cannot be accommodated in the available spacing allowed by the X-ray data.

"Turning, then, to ring formulae which involve the first carbon atom, only two of the five conceivable formulae require consideration, namely, the 1-4, or butylene oxide ring, and the 1-5, or amylenoxide ring structure. The three remaining ring formulae are highly improbable on stereochemical grounds; furthermore, carbohydrates containing such rings have not been found in nature. The possibility of their occurrence in cellulose appears to be definitely excluded by the methylation studies of Irvine and his associates, which show that the second, third and sixth positions are occupied by replaceable hydroxyls, consequently ring formation must occur through the remaining, or first, fourth and fifth positions. Other rings than the 1-4 and 1-5 are, therefore, excluded as possible units in the cellulose structure.

"Irvine and Hirst found that the glucose unit in cellulose was a stable, rather a labile form, and in accordance with conceptions then current, they regarded the unit as having the butylene oxide ring structure. Evidence has since been brought forward by Haworth and by Hirst to indicate that the normal stable form of glucose, and presumably the form which exists in cellulose, contains not a butylene oxide, but an amylenoxide ring. It will be noted that Irvine's data are equally explainable on the basis of either structure. If the unit contains a 1-5 ring instead of a 1-4 ring as was formerly supposed, then the linkage between units would be through the fourth carbon atom instead of through the fifth, but in either case the 2, 3, and 6 positions would remain open for methylation," p. 177.

"A conception of the structure of ramie cellulose is described based on previously published X-ray data and upon studies with stereochemical models. The proposed structure agrees with the space lattice indicated by the X-ray data and is apparently consistent with all of the physical properties and chemical reactions of fibrous cellulose. The cellulose structure is made up of glucose units. Of the various possible structural formulae for glucose, it is shown that the amylenoxide ring formula is in closest agreement with the X-ray requirements. It is accordingly accepted as the probable structural unit of cellulose. The glucose units are apparently united in chains of indefinite length by glucosidal condensation. The union between units is alternately a 1-1 and a 4-4 linkage. The X-ray data indicate that the 1-4 linkages, characteristic of cellobiose, do not exist in the ramie cellulose structure," p. 201.

"With a certain limited number of exceptions, solvents for the common cellulose esters are non-solvents for rubber, and, conversely, solvents for rubber are non-solvents for the cellulose esters. Speaking very broadly, the case may perhaps be stated thus: cellulose nitrate and acetate, representing a trihydric compound esterified with respectively an inorganic acid and a fatty acid of low molecular weight, are polar substances and in general imbibe and yield sols with polar organic liquids, *i. e.* with the lowest members of organic series containing active groups, while rubber, a hydrocarbon, is non-polar and in general imbibes most freely and when unvulcanized yields sols with liquids of low polarity, *i. e.*, with hydrocarbons, halogenated hydrocarbons, and the higher members of series containing active groups. In general, compounds containing active groups are swelling agents for rubber only if they contain as well hydrocarbon residues of some length; and, the larger

the hydrocarbon residue, the greater is the extent to which they are imbibed. Conversely, long hydrocarbon residues are unfavorable and active groups favorable to the dispersion of cellulose esters. Compounds containing active groups are solvents for the cellulose esters only if the hydrocarbon residue present are small. Consider the behavior of rubber and of cellulose acetate to a number of types of compounds," p. 205.

"Following the general considerations regarding the influence of the chemical constitution of liquids on the behavior of organophilic colloids which have been outlined in the above comparison of rubber and cellulose acetate, some observations were made on the behavior of metastyrene in various liquids. And it was found that this colloid, which, like rubber, is a hydrocarbon, in general swells and disperses in liquids of the same types as those in which rubber swells and fails to swell in liquids which are non-solvents for rubber but good solvents for cellulose acetate. In the case of meta-styrene, as in the case of rubber, increase in the length of the hydrocarbon residues present in a given type of organic molecule tends to increase ability to produce swelling and dispersion.

"Owing probably to the lower mechanical strength of swollen meta-styrene as compared with that of swollen rubber, meta-styrene usually disperses more easily than rubber. It was found, for example, that, where meta-styrene is insoluble in the lowest member of a given homologous series, it is not usually necessary to ascend the series so far as in the case of rubber in order to encounter a solvent. But this quantitative difference from rubber does not obscure the fact that broadly the same generalizations regarding the relation between chemical structure and swelling power hold for meta-styrene as for rubber. Some examples will serve to illustrate the parallelism between the behavior of meta-styrene and rubber and the contrast between metastyrene and cellulose acetate," p. 210

"Consider now the question of the role of solvation in the viscosity of sols of organophilic colloids. Although the electrical charges on the particles may play a certain part in the viscosity of such sols, they apparently never play more than a comparatively small part. And the question arises as to whether the major rôle in the viscosity of sols of organophilic colloids is to be ascribed to solvation or to some other cause, such as, *e. g.*, the existence of structure in the system. In the case of sols of nitrocellulose, McBain has recently expressed the opinion that the high viscosity is due for the most part not to true solvation, but rather to the immobilization of solvents owing to its being enmeshed in a loose structure formed by cohering and ramifying rigid colloid particles or micelles. He bases this opinion in part on the fact that sorption experiments show the degree of solvation of nitrocellulose to be not more than 100 per cent of the weight of the nitrocellulose—a degree altogether too small to account for the observed viscosities.

"There is reason to believe in the case of certain other and probably in the case of many other organophilic colloid sols that the degree of solvation is much greater than that just mentioned, and consequently that solvation plays an important if not a major part in producing high viscosities. For example, rubber can readily be ascertained to imbibe 2000-4000 per cent of its weight of solvent when placed in certain liquids. When raw rubber is immersed in a liquid of high swelling power, *e. g.*, benzene, o-dichlorobenzene, carbon tetrachloride, it will be found to have increased in weight 20-40 times after 24 hours; it will thereafter gradually lose weight owing to diffusion of the swollen rubber into the liquid. And the actual degree of solvation of rubber by good swelling agents is almost certainly even higher than the increase in weight when a piece of rubber is immersed in the liquid, since diffusion of the solvated rubber out of the swollen gel begins before the piece as a whole has reached its maximum swelling," p. 218.

"Raw rubber, even when entirely free from the resin and protein which naturally accompany it, is still highly elastic. It certainly contains no free liquid phase. And it seems to me doubtful whether it can be considered as a two-phase system in the ordinary sense of the term. If different phases are in fact present, it would appear that the less rigid phase or phases can only be a part of the hydrocarbon less highly polymerized than the rest. And the chemical and physical properties of this less highly polymerized part must be so similar

to those of the more highly polymerized part that the two parts must be associated so closely, the higher polymer being, as it were, solvated by the lower, that they do not represent two separate phases in the ordinary sense of the term.

"In this connection some observations made with meta-styrene seem to be illuminating. Meta-styrene is a hard solid. In massive pieces or films it is clear; as precipitated, white. It shows no evidence of the possession of elastic properties: the films are brittle, and the powder friable. Yet it acquires elastic properties when swollen. If it is precipitated, *e. g.*, by acetone or alcohol, from a solution in, *e. g.*, xylene, benzene, or chloroform, the fresh precipitate is strikingly elastic; it is reminiscent of raw rubber; it is even more extensible than raw rubber, and it recovers from extension with a "snap". If the precipitated material is allowed to stand in the air, it gradually loses its extensibility, and when all the solvent has evaporated the remaining metastyrene is white and friable. That is to say: while in a swollen condition, meta-styrene is elastic; when unswollen, it is hard and brittle. A permanently elastic material can be obtained by incorporating with meta-styrene a non-volatile swelling agent, *e. g.*, tricresyl phosphate or isoamyl phthalate. As showing that a swollen condition is necessary for the appearance of elasticity in metastyrene, it may be mentioned that an inextensible material is obtained if, instead of a swelling agent, a non-volatile liquid without swelling properties is incorporated with meta-styrene. Such a liquid is cyclohexanol or high-boiling paraffin (*e. g.*, "Glycoline"). Both these liquids are so completely lacking in swelling power for meta-styrene that they will precipitate it from solution. And if they are incorporated with meta-styrene, the product is inelastic.

"Here then is a case of a rigid organophilic colloid which can be rendered elastic, not by causing it to form the solid phase in a solid-liquid system (the case of meta-styrene + cyclohexanol), but by merely causing it to swell. In writings on the two-phase nature of elastic gels, a solvated solid phase has been regarded as a single phase, free liquid being the other phase. "Elastified" meta-styrene is then in this accepted sense, a one-phase material.

"It would seem that, although elastic jellies, such as those from gelatin and cellulose acetate, may be two-phase systems, elastic colloids such as rubber and "elastified" meta-styrene, which are distinguished from elastic materials of the first class by their much greater elastic extensibility, are not two-phase systems, at all events in the same sense.

"The so-called plasticizers often used along with cellulose esters, with such objects as reducing brittleness and increasing flexibility, are probably "elastifiers," using this term in the sense indicated above in connection with meta-styrene; that is to say, they are non-volatile swelling agents used to improve the extensibility of the esters," p. 221.

"Valuable as the thermodynamic theory of solutions has proven to be, it has, however, given us practically no information as to the actual mechanism of osmosis. Further, with our present limited knowledge of the properties of solutions, it can aid us practically not at all in predicting the osmotic force which may be expected in systems with membranes which are not truly semipermeable and with which we have capillary effects of unknown considerable magnitudes. It is well known that osmotic flow can be obtained through membranes which are far from being strictly semi-permeable. In such systems fairly great osmotic forces are set up, and pressures of considerable magnitude are obtained, though "maximum osmotic pressure" values are never reached. In some cases we find that the operation of the osmotic force (and at least the initial direction of flow of liquid) is, in fact, opposite to that which apparently is demanded by the thermodynamic potential of the liquid system. In such cases the membranes must surely play an active part. It is, then, not surprising that osmotic theories based upon experimental results obtained with such systems as these should be different from those theories which have been obtained from systems having truly semi-permeable membranes," p. 234.

"The writers are inclined to picture conditions during the making of a glue joint in some manner such as the following: The glue, whether it be animal, casein, blood albumin, starch, or perhaps even sodium silicate, is applied to dry wood in the form of an emulsified sol of such concentration as is necessary to give a fluid of convenient consistency to spread properly with the woodworkers' machinery and to penetrate the wood cavities to some extent in order to increase the surface area available for adhesion. As already mentioned, penetration

will be obtained only if the glue wets the wood. Excessive penetration is undesirable for two reasons,—it wastes glue and may produce "starved" joints. Fortunately the dry wood absorbs water from the glue, such water penetrating to a much greater depth below the surface of the wood than the glue. A microscopic examination of sections through glue joints made with glues of alkaline reaction shows this greater penetration of the aqueous dispersion medium very beautifully, because on staining with phenolphthalein the presence of alkali can be demonstrated far beyond the limits of penetration of the glue jelly. Presumably hygroscopic moisture is drawn in still deeper than the dissolved alkalies," p. 261.

"That specific adhesion is an important factor in obtaining strong wood joints will be clear on further considering the results of the shrinkage of glue during drying. If the glue did not stick to the wood, the tendrils of jelly projecting into the wood cavities would be expected to shrivel and no longer fill the openings. The glue film between the gross surfaces would also be expected to draw away from the wood, arching over the spaces between the openings into the wood cavities. Microscopic examination proves that such is not the case. Shrinkage of the glue tendrils takes place largely by enormous exaggeration of the concave meniscus at the inner end of the tentril, leaving a film of glue clinging to the walls of the cavity. When dry the tendrils become long, hollow cylinders for a great portion of their length. Shrinkage in the main glue film evidently takes place by a decrease in total thickness, drawing the wood surfaces somewhat closer together than they were at the time the glue set," p. 265.

"In a paper given at the Colloid Symposium last year, it was shown that one very important factor for the sensitivity of photographic emulsions is the inherent substance present in the gelatin surrounding the grains. Minute traces of organic isothiocyanates and thiocarbamides in gelatin react with the silver halides to form nuclei of silver sulfide which in turn act as sensitivity centers for light decomposition of the silver halide grains. Theoretically it is therefore possible to separate the process of ripening into two distinct phases, viz., the production of silver halide grains size and composition, and having a given size distribution, and the sensitization of these by inoculation with silver sulfide," p. 281.

"Colloid chemistry of today is based entirely on the connection between the electrical charge and the stability of the colloidal particles. This relation was first discovered by Hardy, was confirmed by Burton, and was later made more definite by Powis. Measurements of the electrical surface-charge in connection with the stability of the colloidal particles are of the greatest importance and, when combined with data on the cataphoresis of colloidal solutions, must give the most needed information as to the nature of colloidal solutions. Recently one of us has shown what difficulties there are in exact measurements of cataphoresis and this paper gives chiefly the results of a study of cataphoresis in which as far as possible all objections to the technique are avoided. We have chosen the arsenious sulfide sol as the one to study, because Powis obtained results with this very sol which seemed to conflict with his theory of the critical potential, while, on the other hand, the theory described the behavior of other sols extremely well. Powis found that the critical potential, based on cataphoresis experiments in presence of potassium chloride did not agree with that which he had found with other electrolytes, such as barium chloride, aluminum chloride, thorium nitrate, etc. We first attempted to get a better agreement by avoiding, so far as possible, all the errors in the cataphoresis technique. From our results it will be seen that we have succeeded in getting a better agreement between theory and fact, but the outcome is quite different from what we had anticipated," p. 304.

"In de-inking paper the ink is dislodged from the cellulose or other fibers and is brought into suspension in a liquid medium, with which or from which it may be removed. The first stage of the process is one of dispersion, and, since the printed paper is a more or less solid complex of pigment, oil, size, and fiber, a suitable mechanical treatment (pulp) in the presence of a peptizing agent (detergent) will be necessary. In general, the peptizing agent may be an ion or a colloid in solution; the most effective detergent is a substance or a combination of substances which is able not only to peptize the carbon-black (or other pigment) of the ink, but also to emulsify, dissolve, or otherwise attack the oily vehicle of the ink and to aid in the disintegration of the paper. When brought into suspension, the carbon-black

may be removed with the liquid dispersion medium by washing the latter out of the pulp, or it may be allowed to pass into a second liquid, such as an oil, which wets carbon preferentially, or it may be adsorbed at a liquid-liquid or liquid-vapor interface and be removed by flotation. All of these methods have been tried in practice," p. 311.

"The ideal de-inking agent is probably some substance, preferably a colloid, which is adsorbed much more strongly by ink than by paper, and tends to peptize ink. If the substance is a colloid and is adsorbed more strongly by paper than by ink, a mordanting action results, which tends to bind the ink to the fiber. Such an effect has been observed with albumin," p. 326.

"Purified charcoals have been found to have no adsorbing action on iron oxide sols of the type known as Graham iron oxide sols. Technical grade charcoals have high removal powers on iron oxide sols and in this removal any adsorption effect is wholly negligible, the removal being due to the precipitating action of the electrolytes present in the charcoal as impurities," p. 353.

"If the membrane of a living cell is a colloidal film similar to a colloidal sol that can undergo reversible coagulation, there would appear to be a close analogy between the action of salt pairs in the precipitation of such sols as copper ferrocyanide and arsenious sulfide and the antagonistic action of salt pairs on the permeability and hence on the life and growth of living cells. From this point of view, all of the factors influencing the precipitating action of salt pairs as it effects the stability of sols, which I have outlined above, will be concerned in the antagonistic action of salt pairs as it affects the permeability of protoplasm," p. 372.

Wilder D. Bancroft

Handbuch der Physik. Edited by H. Geiger and Karl Scheel. Vol. X. 26 × 17 cm; pp. viii + 486. Berlin: Julius Springer, 1926. Price: 35.40 marks, paper; 37.50 marks, bound. This volume deals with the thermal properties of substances and is under the special editorship of F. Henning. The chapters are entitled: the solid state; fusion, freezing, and solidification; gaseous and liquid states; thermodynamics of mixtures; specific heat (theoretical part); specific heat (experimental part); determination of free energy; thermodynamics of solution.

The reviewer has found in the book a number of tables which were useful to him personally, and, doubtless, others will have similar experiences.

"If we include under the law of corresponding states those relations which follow from the identity of form of the equations of state for different substances, and if we separate from it the mechanical principle of identity, we may say that the second principle does two things. It accounts for the law of corresponding states holding and it also says that similar relations must hold in cases in which it is impossible to use the law of corresponding states in its narrower form. Most of the applications deal with the law of corresponding states in its narrower form. It has proved very useful; but it is not an absolute law and different substances show different variations," p. 196.

It was new to the reviewer that melting anethol (21.6°) or melting orthocresol (31.1°) could be used instead of melting ice in the ice calorimeter, p. 331. When one plots the difference of the atomic heats of white and gray tin divided by the temperature against the temperature, there is a tremendous maximum at about 30° abs. Measurements of specific heats down to the temperature of liquid air would be quite inadequate in showing the true form of the curve, p. 362.

"Let us call attention to the calculation of the dissociation of the fixed stars which has been made chiefly by Saha using Eggert's method. The heat of dissociation into electron and ion is known from optical observations and the specific heats of all the components are those of monatomic gases. If one used the theoretical values for the chemical constants and for the electron, one has all the data necessary for the calculation of the dissociation equilibrium. Of course the astronomical observations are not sufficient to eliminate uncertainties in the constants of the order of one. Actually we reverse the operation and calculate the temperatures of the fixed stars, which are found to be in good agreement with the values obtained in other ways," p. 391.

The book is a little vague on the vapor pressures of three-component systems, p. 456. "For the simultaneous solubility of two substances A and B in the same solvent C, a similar calculation holds. The partial vapor pressures of A and B are no longer proportional to the mol fractions. The condition of saturation gives the definite values of the vapor pressures P_1 and P_2 which are those of pure A and pure B at the temperature in question. Consequently μ_1 and μ_2 [the mol fractions] are not free to vary independently. They are therefore mutually dependent; the change in the solubility of B in presence of A determines the change of the solubility of A in presence of B."

On pp. 476 et ff. there is a supplement on time phenomena. "Since thermodynamics usually takes no cognizance of time, it deals normally with only two sets of processes: those which take place immeasurably rapidly and those which do not take place at all or take place in a time which is infinitely long so far as the thermodynamic considerations are concerned." This is a very unfortunate wording because thermodynamics does deal with no end of systems in which equilibrium is reached slowly; but we wait until equilibrium is reached before applying thermodynamics.

"As a matter of fact there are very many cases both with pure substances and with solutions, in which an assumed change does not take place practically instantaneously or in which the system does not remain unchanged in the theoretical sense during the time necessary for testing the formulas. There is often, however, the possibility in the first case of accelerating the process or of considering it accelerated by means which do not affect the thermodynamically considered state, and in the second case of retarding the change. While the full discussion of such changes or assumptions belongs under the theory of reaction velocity, we must at least point out here for what thermodynamical conceptions and relations, these things must be considered, especially in the case of solutions. . . .

"If we mix any desired amounts of hydrogen, oxygen, and water vapor at room temperature, there is practically no interaction and we are consequently dealing with three independent components. Presence of liquid has practically only the effect of causing a little of the two gases to dissolve and of giving the partial pressure of the water a practically constant value, depending on the temperature. If the water contains a small amount of colloidal platinum—which can be ignored thermodynamically—there is a slow combination of the gases to form water and the three substances can no longer be considered strictly as independently variable, though this might be considered as approximately true if the reaction takes place sufficiently slowly. If we bring the three gases to a very high temperature, the reaction runs to equilibrium very rapidly and we must consider the system thermodynamically as made up of two independently variable components and not of three. The intermediate region of slow change cannot be treated thermodynamically.

"A second case to be considered is the liquid mixture of acetaldehyde CH_3CHO and its polymer paraldehyde $(\text{CH}_3\text{CHO})_3$. These two liquids are miscible in all proportions and act like other binary mixtures. If one adds a little sulphuric acid to the mixture, the reaction $(\text{CH}_3\text{CHO})_3 \rightleftharpoons 3\text{CH}_3\text{CHO}$ runs to equilibrium, the direction of the reaction depending on the initial relative concentrations. The solution then behaves thermodynamically like a one-component system. On distillation one gets practically pure acetaldehyde, because the paraldehyde has a much lower vapor pressure and depolymerizes as the acetaldehyde distills off. On the other hand nearly pure paraldehyde separates on freezing, because the freezing-point of the paraldehyde is more than 100° that of the acetaldehyde and this latter polymerizes as the paraldehyde separates."

Wilder D. Bancroft

Gmelins Handbuch der anorganischen Chemie. Part I. Edited by R. J. Meyer. Eighth edition. 26 × 18 cm; pp. xli + 251. Leipzig and Berlin: Verlag Chemie, 1926. This new edition is very welcome. The first part deals with the noble gases. After a short historical sketch and a longer one on the occurrence of the noble gases, there are chapters on the preparation, general properties, and physical properties of helium, neon, argon, krypton, xenon, and the emanations respectively. After these there are a few pages on the chemical be-

havior of the noble gases, on their detection and determination, and on their uses. The monograph does not come down to the solidification of helium, the literature being considered up to July, 1925.

"Liquid helium is extremely mobile and no increase in viscosity can be noticed even at the lowest temperatures. It has also a very low index of refraction and a very low surface tension, so that it is hard to detect the liquefaction because the meniscus runs to the wall of the vessel perfectly horizontal, as with a liquid near its critical point. It is only at temperatures below 2° abs. that the liquid shows any capillary rise against the glass wall," p. 43.

"An instable diatomic helium molecule is considered to be the cause of the band spectrum. He_2 must be constituted like He. On account of the chemical inertia of the normal helium atom, a formation of a diatomic helium gas must be due to the metastable orthohelium, which, from electron experiments, is twenty volts less than ordinary helium," p. 58.

"Kamerlingh Onnes observed that, with helium-hydrogen mixtures at temperatures at which the hydrogen has liquefied, the gaseous helium may be denser than the liquid hydrogen. We may consequently have a liquid layer floating on a gaseous one," p. 59.

"Helium diffuses slowly through tin and lead foil. Iron and palladium are still impermeable to helium at 950° , platinum at 1000° , and platinum-iridium vessels even at 1420° . On the other hand helium diffuses through quartz glass, about one percent passing through per hour at 215° , nine percent at 500° , and twenty-five percent at 1100° ," p. 69.

According to Dewar the molecular heat of adsorption of helium by coconut charcoal is 483 cal., p. 72. Presence of mercury vapor makes some helium lines disappear while others remain in full strength. The latter belong to the parhelium spectrum while the former are all ascribed to the orthohelium spectrum. In presence of hydrogen helium can only be detected spectroscopically when it exceeds ten percent in amount, while 0.001% hydrogen can be detected in helium, p. 80.

Argon can be made to give a red, a blue, or a white spectrum, p. 152. Kirschbaum believes that the red spectrum is due to univalent argon ions and the blue spectrum chiefly to bivalent argon ions and perhaps, to some extent, to trivalent argon ions, p. 155.

Krypton consists of six isotopes and was the first element in which two isotopes differing by only one unit were observed, p. 170. The writer of the section on krypton does not believe that krypton plays any important part in the Northern Lights, p. 178. In the first place, it is believed that krypton cannot occur at the heights at which the polar lights are seen and, in the second place, the strong yellow line of krypton does not appear in the spectrum of the Northern Lights. Consequently the green krypton line cannot coincide with the green line in the aurora.

There are nine isotopes of xenon, the largest number yet found for a single element, p. 182. "The three emanations, RaEm, ThEm, and AcEm, are isotopic elements. They form colorless, chemically inert, gases, which on account of their radioactive radiation ionize the surrounding air and deposit an active precipitate of their decomposition products on all surfaces with which they are in contact. Liquid radium emanation boils at -62° and solidifies at -71° . It is colorless and transparent in transmitted light; but causes the walls of the vessel to phosphoresce, quartz glass phosphorescing blue, soda-lime glass lilac, and a potash-lead glass bluish-green," p. 199.

Neon apparently forms no hydrates; argon forms one with 4-6 mols of water. Krypton forms a definite hydrate with five of water. Xenon forms a hydrate with six or seven of water, p. 224.

The helium gas thermometer is an important instrument for low-temperature work. Liquid helium is used to give very low temperatures for the measurement of the resistance of super-metals. With liquid helium one can get down to about 1° abs. Liquid neon is used for thermostats that are to be kept at -246° to -249° . Cooper Hewitt mercury vapor lamps and Moore tubes often have argon or neon added. With a mercury vapor lamp containing 25% neon and 75% helium, the light efficiency is about double what it is with neon alone. Argon-filled incandescent lamps are a regular article of commerce. Arc recti-

fields filled with noble gases are used with currents up to 150 amperes. Neon tubes are used to detect static charges. Nutting has recommended the use of helium tubes as light standards and the use of helium in dirigibles is very important, pp. 248-250.

Wilder D. Bancroft

Das Polarisationsmikroskop, seine Anwendung in der Kolloidforschung und in der Färberei. By Hermann Ambronn and Albert Frey. Vol. V. 21 × 15 cm; pp. x + 196. Leipzig: Akademische Verlagsgesellschaft, 1926. Price 12 marks paper; 13.50 marks bound. This book is Vol. V of the series "Kolloidforschung in Einzeldarstellungen," edited by R. Zsigmondy. Part one is devoted to a discussion of methods, in which the emphasis is on the theory of the polarization microscope and of the observations for which it is employed. After introductory chapters on the properties of light and various phenomena exhibited by optically isotropic and anisotropic substances are described in some detail. The treatment is exact and logical, with a minimum of mathematics, and dwells more on somewhat unusual features than is common in similar works. Dispersed double refraction, for instance, is treated in considerable detail and the various types of compensators are described in an exceptionally thorough manner. Dichroism, conoscopic observations, the determination of refractive indices, and the construction of the polarizing microscope are also taken up. The exposition of all this is excellent, but it is likely to be of more use to the experienced microscopist than to one who is making a first attempt to apply the polarizing microscope to his problems. The preciseness, the careful qualifications, the lack of profusion of simple diagrams, of necessity presuppose a thorough grounding in elementary "optical crystallography" to which the book offers an excellent supplement.

The second part of the work deals with double refraction phenomena of dispersoid systems; rod- and plate-double refraction are discussed in detail, as are the combinations of these with optical anisotropy inherent in the substances themselves. Strain anisotropy, flow anisotropy, and liquid crystals also are considered. Various methods of investigating the submicroscopic fine structure of dispersoid systems are given in part three. Imbibition, applied mechanical or electrical stress, and indirect methods are explained, and the behavior of cellulose esters, zeolites, waxes, fibrous alumina, celluloid and the pleochroism of dyed fibers are interpreted in terms of the principles laid down in the preceding sections of the book.

On following through the reasoning which has been applied in the above cases, it is evident that the introductory theoretical treatment was not unduly rigorous, and that one can hardly hope to work out the explanations of new problems without such a foundation. However, there are plenty of people who are concerned primarily with the application of this knowledge, and who need not be able to derive all of it for themselves. One may utilize the change of "sign of elongation" as an indication of the degree of nitration of cellulose, strength of double refraction as an aid in the identification of textile fibers and other tissues, polarization of scattered light as a distinction between fluorescent and colloidal solutions, without bothering about the theory of the phenomena or even of the methods by which they are observed. To such persons the present work will not be particularly suggestive for it does not purport to be a manual, or a piece of propaganda for the use of the polarizing microscope. To the many workers who are trying to form a unified concept of the nature of fibers, gums and similar colloids the book presents some highly stimulating theories and methods of investigation in this field.

C. W. Mason

Lubricating Oil Salesman's Primer. By Claude Ettele. 22 × 16 cm; pp. vi + 118. Easton: The Chemical Publishing Company, 1926. Price: \$3.00. In the preface the author says: "Lubrication is one of those common operations for which there is no adequate theory, yet it is rapidly developing into a science. Knowledge of lubrication consists of a broad knowledge of machinery and industrial processes; of bearing designs, oiling devices and lubricating systems; of the manufacture and nature of lubricants; of physical and

chemical tests which will define and identify lubricants and indicate their properties; and finally, of how lubricants perform in service. A machinery expert knows machinery and lubrication systems, a petroleum chemist is familiar with the nature of lubricants, but neither can be a successful lubricating oil salesman without experience in applying oils.

"A salesman's own experience is his most valuable asset and he is in a position to accumulate first-hand information. But a study of the experience of others is necessary to hasten his productivity. . . . It is hoped this little book will properly present a first view of the subject of lubrication and will encourage the young salesman to study advanced works without which he will be unable to develop maximum efficiency in the services of his employer and of his customers."

The subject is presented under the headings: friction and lubrication; the manufacture of lubricating oils; tests; a line of lubricants; lubrication of prime movers; lubrication of power transmission machinery; lubrication of driven machines.

The author is not a believer in the use of fixed oils, p. 14. "Oils of animal, vegetable and fish origin are called 'fixed' oils because they cannot be distilled. Originally they were the only lubricants, but the advent of mineral oils quickly displaced them to a point where now they are used only in compounds of special oils. A characteristic of fixed oils is their readiness to form emulsions when mixed with water and this is the property taken advantage of in practically all cases where they are used when compounded with mineral oils. They have, however, features desirable in lubricants; they have high heat-resisting powers in that they have high flash points and hold their body when heated, but other characteristics are not desirable in lubricants, their readiness to oxidize and form gummy deposits and their fatty acid content which corrodes metals.

"A quality of fixed oils is their so called "oiliness" which may be expressed as their ability to wet metal surfaces. This property is the basis of the loudest claims in their favor, but it is always true that for every purpose of lubrication a mineral oil can be found to render most economical service. In fact, there are some machines which would have been probably impossible to develop along their present lines were it not for the peculiar properties of mineral oils as lubricants."

"All fixed oils contain fatty acid, which when free and uncombined is corrosive. For this reason practically all specifications of spindle, machine and engine oils will contain a prohibition of any presence of animal or vegetable oils. An exception to this is the marine engine oil, the last stronghold of fixed oils as lubricants. Early types of marine engines required an oil that would emulsify and not be washed away by the large amount of water always present on early types of marine engines. At first mineral oil was used as an adulterant which adulteration increased to a point where now some well-considered marine oils contain as little as 5 per cent of a fixed oil. Marine engineers' prejudice for an emulsifying oil is rapidly decreasing, and, in fact, the use of automatic lubrication on modern marine equipment necessitates the use of mineral oil," p. 15.

Konstanten der Atomphysik. By *Walter A. Roth and Karl Scheel*. 27 × 20 cm; pp. 114. Berlin: Julius Springer, 1923. Price: \$2.00. This is a separate issue in convenient form of a portion of the fifth edition of Landolt-Börnstein-Roth-Scheel: "Physikalisch-chemische Tabellen." The thirty-two tables include: atomic weights; periodic system of the elements; mixtures of isotopes in the elements; radioactive and accompanying inactive isotopes; radioactive elements; heat evolution from radioactive substances; determination of age of minerals; conversion tables for the different energy units; velocity of light in vacuo; recent determinations of N; velocity, free path, and dimensions of gas molecules; minimum thickness of films; literature on gas molecules and minimum thickness of films; values of e , of the electrochemical equivalent, and of related constants; specific charge of the electron; Planck's constant; radiation constants; wave-lengths and spectral regions for the whole spectrum; infrared wave-lengths; optical series spectra for several elements; excitation and ionization voltages for monatomic and polyatomic gases and vapors; numerical values for the "terms" in the spectrum series; absorption and scattering of Röntgen rays; crystal structures;

velocities of the ions for the most important gases and vapors; diffusion coefficients for gas ions; coefficient of mutual recombination of the ions in different gases; discharge voltages in gases; cathode drop in glow discharge; passage of electrons through matter; long-wave limit of photo-electric action; resonance wave-lengths for selective photo-electric action.

A Condensed Collection of Thermodynamic Formulas. By P. W. Bridgman. 24 × 16 cm; pp. 34. Cambridge: Harvard University Press, 1925. Price: \$1.50. In the preface the author says: "A shorter version of the following collection of thermodynamic formulas was published in the *Physical Review* for April, 1914. Continued use of the formulas since then, both personally and in teaching thermodynamics, has convinced me that they are sufficiently useful to justify placing them in a more permanent and accessible form. The formulas as originally given applied only to systems for which pressure and temperature were a possible set of independent variables. An additional table is now given for the first derivatives of systems in which the pressure is a function of temperature, and temperature and volume are a possible set of independent variables. A two-phase system, such as water and steam in contact, is the most important example of such a system. I have further added a number of illustrative examples, worked in detail, to show the method of using the tables. Finally, I have discussed how in a number of cases the formulas may be extended, with very slight changes, to systems subjected to other external forces than a hydrostatic pressure, and have illustrated this extension by several examples."

The author discusses the first and second derivatives and then gives four tables: the fundamental ten quantities—notation and definitions; the first derivatives, p and τ independent variables; the first derivatives, p a function of τ — v and τ independent variables.

After this there are six pages on the use of the tables, two pages on the extension of the tables to systems in which pressure is not the only mechanical variable, and three pages on the use of the tables for other variables than P and v . This last section includes the Helmholtz formula for the relation between electromotive force and heat of reaction.

This seems to the reviewer a distinctly valuable little book. It would have been a little easier on the student if the author had not made x_2 constant when writing his partial differential on p. 4 and x_1 constant when discussing it.

Wilder D. Bancroft

Edible Oils and Fats. Their Substitutes and Adulterants. By G. D. Elsdon. 26 × 17 cm; pp. xix + 521. London: Ernst Benn, 1926. Price: 45 shillings. The author commences his preface with the statement that it would be difficult to write a book on the chemistry and examination of oils which is entirely different from its predecessors, and this is indeed a true saying. The realisation of a difficulty often carries one far in the overcoming of it; for it may be well said of this book that it has points of difference from almost all of the many that have been produced on this subject.

To fill about 500 pages of close print with data in a highly concentrated form is no light task, yet that is what the author has achieved—and done it well.

The book is not without its misprints and mistakes, but they are relatively few and one is much more impressed by the care with which figures, data, and references have been checked than by an odd slip here and there, such as in the mis-spelling of botanical names, and other errors mostly too obvious to be misleading.

The work is essentially a compilation and constitutes a very complete collection of the published work on the subject right up to the moment of publication; and while one is assured that the unusually large number of references has been checked from the proofs of their respective journals, the busy worker cannot fail to appreciate the wisdom of providing references to the abstracts in *The Analyst* and the *Journal of the Society of Chemical Industry*, which are so readily accessible in most laboratories.

The title "Edible Oils and Fats" is a wide one, yet the scope has been freely exceeded. Practically every known oil or fat is described, whether edible or not, including those of rare vegetable origin; while glycerine and dairy products are also dealt with.

The introduction to the book is followed by a clear and concise survey of the properties and composition of oils and fats, their individual glycerides, acids, and alcohols, with methods for the examination and separation of fatty acids.

Some thirty pages are devoted to a description of the physical tests which are usually applied to oils and fats. To those who are mainly interested in physical chemistry this may seem a small proportion of the book, but when one comes to examine this section in detail one cannot fail to admit that no physical test of importance has been omitted, while those described are, for the most part, adequately dealt with in clear and simple language. On going into details one cannot pass without comment the suggestion that the specific gravity bottle or pyknometer gives a higher degree of accuracy than is really necessary. Such a suggestion calls for a warning to the effect that the weight of liquid oils now shipped in very large bulk is calculated from a measurement of the tanks together with a very accurately-determined specific gravity.

The author has in a measure compensated for this lapse by providing a very clear drawing and specification of a delicate pyknometer and a description of its use, but no instructions given under the heading of specific gravity tell the worker precisely how to calculate the true weight in air of a litre of oil nor is he warned that, for the purpose of calculating the weight of oil, the reference standard is water at 4°C. weighed in vacuo, and that such a method is now insisted upon by keen buyers in computing the weight of a delivery of oil.

Under *Chemical Tests* one finds in many cases duplication of methods, but the thoughtful author holds out a guiding hand to the perplexed reader under the heading *Method recommended*, and offers to lead him, rightly or wrongly, in the path he himself has chosen. It is a good idea to offer advice to those who want it and, at the same time, to leave those who may know better to make their own selection.

In the matter of the many analytical constants, however, the reader must sift the grain from the chaff for himself, for the figures collected under each oil—having been taken from a wide expanse of literature—must, of necessity, include many misleading results, which results stand out from the more normal figures to the confusion of all, but against most figures will be found the observer's name—thus giving credit where it is due and relieving the author of a responsibility which a compiler is hardly called upon to bear.

The author is to be heartily congratulated upon presenting to his colleagues a truly useful work—a veritable encyclopaedia of analytical data set out in an easy form for reference. Every wise chemist concerned with the wide subject embraced should provide himself with this book, but manufacturers may find themselves less attracted. Many will be found who will not agree with many of the author's comments, but such will have to admit that they are at least the freely expressed opinions of one who is not afraid to state his thoughts, and even if they appear one-sided they are certainly not illogical and are presented in such a way as to command respect.

E. R. Bolton

Einführung in die Phasenlehre und ihre Anwendungen. By Alexander Findlay. Second edition. Translated by Max Albert Bredig. 24 × 17 cm; pp. x + 248. Leipzig: J. A. Barth, 1925. Price: 13 gold marks. This is Vol. VI of Bredig's "Handbuch der angewandten physikalischen Chemie" and is translated from the fifth English edition, which was reviewed in 1924 (28, 185). It is a pleasure to see that there is such a demand for this book in the German-reading countries.

Wilder D. Bancroft

STUDIES ON THE FORMATION OF LIESEGANG RINGS

BY PHANI BHUSAN GANGULY

In the following pages an attempt has been made to study the Liesegang phenomenon from a colloid-chemical point of view.

Peptisation plays an important part during the formation of periodic precipitates in gels. Gelatine, agar-agar, etc, which are generally used for the formation of periodic structures have, as is well known, very pronounced stabilising properties. During an experiment on the growth of Liesegang rings, say in a test-tube, the concentration of the gel is the same throughout for that experiment, consequently whatever peptising or other influences it exerts are present more or less throughout the whole mass. What however are changing from layer to layer are the concentrations of the reacting substances. It thus becomes evident that in order to get a better understanding of the phenomenon, in addition to the stabilising influence of the gel, the influence of the presence of an excess of one of the reacting substances, on the nature of the newly formed substance, must be definitely known.

It is well known that the charge on a colloid particle can in many cases be traced to the presence of adsorbed ions. In certain cases by the introduction of suitable ions, the sign of the charge can be changed at will.¹ Lottermoser² obtained silver halide sols which were positively or negatively charged according as an excess of silver salts or of the halide salts was used. Thus the sign of the charge was directly dependent on the nature of the common ion which was present in excess and was capable of being adsorbed by the precipitate. Evidently then if silver chromate be capable of adsorbing both silver and chromate ions, one would expect the presence of an excess of either of these ions to have a distinct influence on the nature of the freshly precipitated silver chromate, it may be produced in any form from that of a coarse precipitate to that of a well dispersed colloidal sol. In the following experiments therefore, the stabilisation of the chromates of silver and lead by gelatine and agar-agar respectively, and, what seems more important, the influence of an excess of one of the reacting substances on the nature of the newly formed substances, have been studied.

An attempt has also been made to calculate the concentrations of the reacting substances at different layers of the gel, by means of a formula derived from Fick's diffusion equation in the following way.

Let us consider a column of gel of length l , with a concentrated solution of silver nitrate, say 0.5 M, diffusing into the gel from the top region OE, with a certain amount of potassium chromate uniformly distributed throughout the gel from O to F. We shall first consider the distribution of silver nitrate in the gel after any time t , neglecting for the time the presence of

¹ Cf. Mukherji: *Trans. Faraday Soc.*, 16 (Appendix), 103 (1921).

² Lottermoser: *J. prakt. Chem.*, (2) 75, 293 (1907).

potassium chromate in the gel. Since the concentration of silver nitrate is fairly large, if t be not very great, we can reasonably suppose that the concentration of silver nitrate at O remains constant. The diffusion follows Fick's law,

$$\frac{\delta v}{\delta t} = D \frac{\delta^2 v}{\delta x^2} \quad (1)$$

At any layer B at a distance x from the top at any time t , the concentration of silver nitrate is given by:

$$v = C \left\{ 1 - \frac{2}{\sqrt{\pi}} \int_0^{\frac{x}{2\sqrt{Dt}}} e^{-\xi^2} d\xi \right\} \quad (2)$$

FIG. 1

where C is the initial concentration of silver nitrate above O.

writing

$$\theta(x) = \frac{2}{\sqrt{\pi}} \int_0^{\frac{x}{2\sqrt{Dt}}} e^{-\xi^2} d\xi.$$

we have from Equation (2)

$$v = C \left\{ 1 - \theta \left(\frac{x}{2\sqrt{Dt}} \right) \right\} \quad (3)$$

The values of the function $\theta(x)$ for different values of x are known¹ whence the value of v for different values of x can be obtained from equation (3). Now as silver nitrate diffuses in, it reacts with the potassium chromate present and destroys the equivalent amount of the latter. Let us suppose that the concentration of the potassium chromate initially had a value A , and that silver nitrate destroys α times its weight of potassium chromate. Now let us follow the change in the concentration of the potassium chromate after a time interval t . At a distance x in time t , the amount of silver nitrate present

in the gel is, from equation (3), equal to $C \left\{ 1 - \theta \left(\frac{x}{2\sqrt{Dt}} \right) \right\}$

This will react with the potassium chromate and thus destroy the quantity

$\alpha C \left\{ 1 - \theta \left(\frac{x}{2\sqrt{Dt}} \right) \right\}$ of potassium chromate.

The amount of potassium chromate present at the layer D will thus be

$$A - \alpha C \left\{ 1 - \theta \left(\frac{x}{2\sqrt{Dt}} \right) \right\} \quad (4)$$

This will be the amount if there were no diffusion of the potassium chromate. Actually however, the potassium chromate is diffusing simultaneously with the silver nitrate. The change in the value of A , owing to the diffusion of the potassium chromate must therefore be taken into consideration.

¹ Trans. Roy. Soc., Edinburgh, 39, 257 (1899).

The initial condition is that the concentration of potassium chromate throughout OF is A. If OF be sufficiently long and t be small, we have at any time t ,

concentration at O = 0 (Zero)

concentration at F = A.

The diffusion follows the Equation:

$$\frac{\delta v}{\delta t} = D_1 \frac{\delta^2 v}{x^2}$$

Solving this equation with the above mentioned conditions and evaluating the constants as in a Fourier's series, the solution is given by

$$v = \sum \frac{2A}{m\pi} e^{-\frac{D_1 m^2 \pi^2 t}{l^2}} \sin \frac{m\pi x}{l} + \frac{A}{l} x \quad (5)$$

Now when the diffusion of potassium chromate is also taken into consideration we shall have to put the above value of v , in place of A, in equation (4). The amount of potassium chromate present at any distance x , after a time t , would thus be

$$= \left\{ \frac{2A}{\pi} \sum \frac{1}{m} e^{-\frac{D_1 m^2 \pi^2 t}{l^2}} \sin \frac{m\pi x}{l} + \frac{A}{l} x \right\} - \alpha C \left\{ 1 - \theta \left(\frac{x}{2\sqrt{Dt}} \right) \right\} \quad (6)$$

where D_1 is the diffusion coefficient of potassium chromate. This equation has been used to calculate a series of values for the concentrations of the reacting substances at different layers of the gel, and an attempt has been made to locate the approximate positions of a few top bands by correlating these values with the experimental data obtained in this investigation.

Experimental

When a certain quantity of the stabiliser was used to peptise gradually increasing quantities of the precipitate, it was found that the change from transparent sols to turbid precipitates was not sharp enough to make it possible to determine by means of the eye the limiting concentrations corresponding to the maximum amount that can be peptised by a certain weight of the stabiliser. To get a sharp point the nephelometer devised by Kingslake¹ was used with a slight modification. The standard used was a 2% gelatine gel containing 0.05% barium sulphate. Instead of comparing the intensity of the scattered beam, the emergent beam after the incident beam had traversed a column of the liquid under examination, was compared with the standard. The observation tube was cut shorter, and a brass cap C, carrying a mirror m inclined at an angle of 45° to the emergent beam was fixed just above the observation beam. The position of the brass cap was so adjusted that the reflected beam illuminated the central slit usually occupied by the scattered beam. A slit s cut in the side of the brass cap came just in front of the mirror, and thus cut off any light likely to interfere with the standard. The arrangement is shown diagrammatically in Fig. 2.

¹ Trans. Optical Soc., (2) 26, 53 (1923-24).

The maximum amount of precipitate which can be peptised by a certain weight of the stabiliser was first determined. The precipitates were formed by the interaction of the solutions of the respective nitrates with a potassium chromate solution. Gradually increasing volumes of the solutions of the nitrates, which were exactly equivalent to the chromate solution, were added to corresponding volumes of the chromate, the quantity of the stabiliser being

the same in every case. The resulting solutions were then examined on the nephelometer. Experiments were performed with different concentrations of the gelatine. The results obtained are given in Table I, and Fig. 5. In a second series of experiments the quantities of the stabiliser and one of the reacting substances, were kept constant, the other reacting substance being added in gradually increasing quantities. The above experiments were repeated with different quantities of the stabiliser but the same amount of the reacting substances. The results are given in Tables II and III.

FIG. 1 FIG. 2

In the beginning the solutions were mixed by rapidly pouring from one tube into another. Various anomalous results were obtained, which were found to be due to irregular mixing, it being altogether impossible to have homogeneous mixing by any such means. With the help of the apparatus shown in Fig. 3, the solutions could be mixed simultaneously and uniformly. By means of the screw clips at c and c_1 , the flow was so adjusted that the liquids from both the limbs ran out at the same time, there being no lag in the flow. Reproducible results could be easily obtained when this process of mixing was adopted.

TABLE I

10 ccs of solution containing gradually increasing amounts of AgNO_3 and 0.004 gm of gelatine, were each mixed with 10 ccs of exactly equivalent K_2CrO_4 solutions also containing 0.004 gm of gelatine.

Amount of Ag formed	CrO_4	Nephelometric readings	Amount of Ag formed	CrO_4	Nephelometric readings
1.	0.0039	15.4	10.	0.0234	Very clear
2.	0.0078	15.4	11.	0.0254	Very clear
3.	0.0097	11.2	12.	0.0273	19.2
4.	0.0117	11.8	13.	0.0293	17.5
5.	0.0136	12.4	14.	0.0312	13.1
6.	0.0156	16.8	15.	0.0332	9.2
7.	0.0175	18.2	16.	0.0351	7.0
8.	0.0195	19.4	17.	0.0370	Very turbid.
9.	0.0214	Very clear	18.	0.058	Completely precipitated.

From Table I it will be seen that whereas 0.008 gram of gelatine is capable of peptising 0.25 gram of silver chromate in one case, the same amount of gelatine fails to peptise a lesser amount of the chromate viz. 0.0097 gram in another case. It thus becomes clear that peptisation by gelatine is generally dependent on the concentration of the substance peptised, in a remarkably specific way.

The scale reading of the nephelometer is a function of the turbidity of the solutions examined, a higher reading being obtained with a more transparent and consequently better peptised solution, a lower reading corresponding to a semi-transparent or partially peptised solution. If the scale readings from Table I, be plotted a curve (Fig. 4) is obtained which shows two distinct minima. These points correspond to the concentration at which the resulting mixture is more or less a precipitate, the peptising power being at its minimum. It thus becomes evident at once that there are two distinct zones for the concentrations of the reacting substances at which precipitation occurs, even when the quantity of the stabiliser present is capable of producing a transparent sol with a much larger quantity of the precipitate at a different concentration of the reacting substances.

FIG. 3

In Fig. 5 are plotted the results obtained with gelatine solutions of increasing concentration, the reacting substances being mixed in equivalent quantities as before. Similar coagulation zones as in the first case are also obtained with 0.2%, 0.4%, and 0.8% gelatine solutions.

As the concentration of the gelatine solution used increased, the amount of silver chromate formed at the first coagulation zone also increased. This increase is seen clearly from Fig. 6 where the concentration of the gelatine solutions have been plotted against the amounts of silver chromate present at the coagulation zones.

Thus from the above experiments we see that there is no simple proportionality between the amount of the stabiliser and the quantity of the precipitate which it will peptise. For a gelatine solution of given concentration, two equivalent solutions producing silver chromate will have the greatest tendency to form a precipitate only when the amount of silver chromate formed has a value approximating to the quantity at the first coagulation zone or when it has a value in or beyond the second coagulation zone.

In the next series of experiments the influence of common ions on peptisation of the cromates of silver and lead by gelatine has been followed. In these

experiments the concentrations of the gelatine solution and that of one of the reacting solutions were kept fixed, the other reacting substances being added in gradually increasing quantities.

FIG. 4

In Table II the influence of an excess of silver ions is shown, the chromate ions being all used up to form silver chromate. With a 0.08% solution of gelatine there is the maximum tendency for precipitation when the quantities of the reacting solutions are nearly chemically equivalent. The precipitation

FIG. 5

continues till there is an excess of unused silver nitrate. The same weight of silver chromate viz. 0.0084 gm is formed in all mixtures, therefore if precipitation depended on the quantity of the stabiliser only, excess of silver nitrate

FIG. 6

TABLE II

10 ccs of solutions containing gradually increasing amounts of silver nitrate and 0.004 gram of gelatine, were each mixed with 10 ccs of solutions containing .005 gm of potassium chromate and 0.004 gm of gelatine.

Amount of silver chromate formed = 0.00843 gm.

Excess of common ion	Nephelometric readings	Colorimetric readings	Excess of common ion	Nephelometric readings	Colorimetric readings
1. 0.0032 gm AgNO_3	8.4	—	7. 0.0912	Very clear	1.1 cc
2. 0.0053	14.2	—	8. 0.1912	"	1.15 cc
3. 0.0073	18.5	—	9. 0.2912	"	1.35 cc
4. 0.0113	Very clear	—	10. 0.5912	"	1.4 cc
5. 0.0312	"	1.0 cc	11. 1.1912	"	1.5 cc
6. 0.0512	"	1.1 cc	12. 1.3912	"	1.9 cc

having no influence on the process of peptisation, all the subsequent mixtures as they contain the same amount of gelatine, should show the same opacity. On the contrary as the quantity of unacted silver nitrate in the mixture increases beyond a certain limit, an increase in the peptisation of the precipitate sets in, showing thereby that a certain excess of silver nitrate has a distinct stabilising influence. The quantity of free silver nitrate can be increased to an extent without any subsequent precipitation occurring. As will be seen from Table II, No. 12, the amount of silver nitrate which is left unacted upon is about 300 times the weight of silver chromate formed, but the resulting solution is still a peptised sol.

The influence of excess of chromate ions on the peptisation of silver chromate is shown in Table III. As in the above case the maximum turbidity occurs when the reacting solutions are nearly equivalent, there being very little excess of either of the reacting ions left unacted upon. Excess of unacted potassium chromate gradually brings about peptisation till for the mixture No. 8, a very clear completely peptised sol results, which does not get precipitated even when the potassium chromate is present in large quantities. Thus like the silver ions chromate ions also act as a stabiliser.

TABLE III

10 ccs of solutions containing gradually increasing amounts of K_2CrO_4 and 0.004 gram of gelatine, were each mixed with 10 ccs of solutions containing in each case 0.00875 gram of silver nitrate and 0.004 gram of gelatine.

Amount of silver chromate formed = 0.00843 gm.

	Excess of common ion	Nephelometric readings		Excess of common ion	Nephelometric readings
1.	0.002 gm of K_2CrO_4	12.0	6.	0.015	Clear
2.	0.003	12.5	7.	0.025	"
3.	0.004	13.4	8.	0.095	"
4.	0.005	14.5	9.	0.195	"
5.	0.010	18.4	10.	0.495	"

As will be seen from Table III, in presence of an excess of silver ions coagulation of the precipitate occurs only over a certain range of concentration of the free silver nitrate. This range of concentration over which the maximum turbidity occurs, however, shifts in a very remarkable way with the concentration of the gelatine used. Experiments have been performed with different concentrations of gelatine and the results are given in Table IV. An examination of the table shows that as the concentration of the gelatine solution increases, the amount of silver nitrate present at the points corresponding to the zone of maximum turbidity, also increases. Thus with a 0.05% gelatine solution the maximum turbidity occurs when there is practically no excess of silver nitrate, with a 0.08% gelatine solution, the maximum turbidity occurs in the presence of 0.00325 gm of unacted silver nitrate, and so on till finally for the 1.6% gelatine solution the maximum turbidity occurs in the presence of a relatively large amount of silver nitrate viz. 0.01 gram. It would thus mean that the stabilisation of the precipitate by silver nitrate is greatly dependent on the concentration of the gelatine solution used. For a certain weight of silver chromate as the concentration of the gelatine increases, silver nitrate up to a certain concentration seems to act as a coagulating agent, but beyond that concentration it serves to stabilise the sol, which then becomes very stable and does not get precipitated on further increase of concentration of silver nitrate.

TABLE IV

10 ccs solutions containing gradually increasing amounts of AgNO_3 and 4 ccs of a gelatine solution of given concentration were each mixed with 10 ccs of solutions containing 0.005 gram of K_2CrO_4 and the same amount of gelatine.

Amount of silver chromate formed = 0.00843 gm:

	Excess of common ion	Nephelometric Readings. (Concentration of gelatine solutions.)				
		Very turbid		Clear	Clear	Clear

It may incidentally be remarked here that the peptised sols obtained when the excess of silver ions present was beyond a certain limit, showed a gradual increase in the intensity of coloration with increase of the amount of free silver nitrate in the mixture. To follow this change a colorimetric estimation was done. All the various solutions were diluted with known volumes of water so as to bring the depth of coloration to that of one from among the series of mixtures chosen arbitrarily. The results are shown in Table II. It would be seen that, generally speaking, as the quantity of the silver nitrate increased the intensity of coloration of the solution also increased. It seems probable that as the amount of unacted silver nitrate increases, a change in the size of the peptised particle sets in, which brings about a corresponding change in the depth of coloration of the final mixtures.

The peptisation of lead chromate by agar-agar has also been followed. It will be seen from Table V, that wherever there is an excess of lead ions or an excess of neither ion, the maximum turbidity appears. When however there is an excess of chromate ions in solution, a more or less peptised sol is obtained. As the quantity of the chromate ions continually increases the sol at first gets more and more stable, but later on it gradually gets turbid, and finally gets precipitated when the quantity of chromate ions in excess becomes very large. Evidently chromate ions to a certain extent can peptise lead chromate, but lead ions do not seem to have any such peptising influence.

It can be easily shown that lead chromate adsorbs only chromate ions and not lead ions. It is well known that if a substance be precipitated in presence of such ions as it can adsorb, the precipitate can generally be subsequently peptised by washing. This has been done in a number of cases. Thus the

TABLE V

10 ccs of solutions containing different amounts of K_2CrO_4 and 0.004 gm of agar-agar, were each mixed with 10 ccs of solutions containing different amounts of $Pb(NO_3)_2$ and 0.004 gm of agar-agar.

Amount of lead chromate formed = 0.00429 gm.

	Excess of common ion present	Nephelometric readings		Excess of common ion present	Nephelometric readings
1.	0.0057 gm of $Pb(NO_3)_2$	Completely precipitated	7.	0.00028 gm of	7.4 cms
2.	0.0037 "	"	8.	0.00038 "	12.3
3.	0.0017 "	"	9.	0.00048 "	18.0
4.	0.002 "	"	10.	0.00148 "	19.1
5.	0.003 gm of K_2CrO_4	"	11.	0.00198 "	18.5
6.	0.00018 "	"	12.	0.00248 "	17.2

silver chromate precipitated in presence of an excess of either silver ions or chromate ions, could under both the circumstances be easily peptised by subsequent washing. Evidently then silver chromate is capable of adsorbing both silver ions and chromate ions. When lead chromate was precipitated in presence of an excess of lead ions, the precipitate could not be subsequently peptised at all by washing. This clearly shows that lead chromate can adsorb only chromate ions but not the lead ions. Thus it explains the ability shown by chromate ions alone, of peptising lead chromate.

The sign of the charge of the peptised silver chromate was determined in a number of cases, and in every case it was found that it was guided by the nature of the free common ion present, being positive when an excess of silver nitrate was used to peptise the sol, and being negative in presence of an excess of chromate ions. This clearly shows that peptisation by one of the reacting substances is brought about by an adsorption of one of the common ions, the resulting sol having the same charge as the adsorbed ion.

As a result therefore of the foregoing experiments one is thus led to the conclusion that a solution of silver nitrate reacting with a potassium chromate solution, will form a turbid precipitate of silver chromate only when one of the following two conditions is fulfilled:—

(1) Unless very concentrated, if the two reacting solutions be equivalent, they will be precipitated only when the quantity of silver chromate formed is a certain definite amount (which will be dependent on the concentration of the gelatine solution used.) When the quantity of silver chromate formed is either greater or smaller than this amount, a peptised solution will result.

(2) When one of the reacting substances is used in excess, for a given weight of silver chromate and a given gelatine concentration, precipitation will occur only when a certain concentration of one of the reacting substances is left in excess. If the amount of the substance left in excess be greater or less than this quantity, a peptised sol instead of a precipitate will result.

The same sort of condition will presumably hold for the case of lead chromate, but there will be the important difference that whereas in the case of silver chromate both the ions will have a peptising influence in the case of the lead chromate, lead ions will not function at all in its peptisation.

These results thus throw a great deal of light on the Liesegang phenomenon. To take the case of silver chromate rings in gelatine, as the silver nitrate diffuses into the gel, it meets the potassium chromate in all different relative concentrations. But as we have seen above precipitations will occur only in those layers where the conditions given above are fulfilled. One would thus expect the silver chromate to be formed as a precipitate in certain layers and as a peptised sol in other layers. The same will probably happen in the case of lead chromate. But in the case of lead chromate as one of the factors producing peptisation is absent viz. the peptising influence of the lead ions, the frequency of occurrence of the precipitate layers will be greater, which seems to be quite in accordance with the actual experimental structures obtained with lead chromate in gelatine gels. It appears now that it will be interesting to calculate the distribution of concentrations of silver nitrate and potassium chromate in different layers of the gel. By using Equation (6) a series of values have been calculated and are given in the following table. The value of D_1 , the diffusion coefficient of K_2CrO_4 , could not be found in any of the usual tables. It has been calculated by using Nernst's equation viz,

$$D = RT \frac{2uv}{u+v}$$

which when expressed in C. G. S. units gives

$$D = 0.04485 \frac{uv}{u+v} [1 + 0.0034 (t - 18)].$$

(cf. Nernst: "Theoretical Chemistry," pp. 435.)

Taking $t = 12^\circ$, $u = 64.5$, and $v = 72$,¹ we get the value of $D_1 = 1.49$ for a dilute viz a $M/300$ (about 0.0065%) solution of potassium chromate. The value of D , the diffusion coefficient of silver nitrate, has been obtained by plotting the values of Thovert² for different concentrations of silver nitrate. The value for a 0.5 M (8.49%) solution of silver nitrate is thus found from the curve to be 0.933. These values of D and D_1 have been used in the following calculations.

The series $\sum \frac{1}{m} e^{-\frac{D_1 m^2 \pi^2 t}{l^2}} \sin \frac{m \pi x}{l}$ was found difficult to sum, so in the

following calculations sufficient number of terms have been taken in order to get values correct to the second place of decimals. Taking $t = 1$ hour and $l = 10$ cms, a series of values have been calculated and are given in the following table. (Table VI.)

An Explanation of Liesegang Ring Formation

In the foregoing experiments it was found that two equivalent reacting solutions will give a precipitate only when forming a definite amount of silver chromate, the amount depending on the concentration of the gelatine solution used. The values obtained experimentally for different gelatine concentrations are given in Table VII:

TABLE VII

	Concentration of gelatine solution.	Amount of silver chromate formed at the first precipitation point.
1.	0.04%	0.009 gm in 20 ccs, i. e. 1/367 N. Ag_2CrO_4
2.	0.1%	0.01 gm in 20 ccs, i. e. 1/330 N. Ag_2CrO_4
3.	0.2%	0.0133 gm in 20 ccs, i. e. 1/248 N. "
4.	0.4%	0.0149 gm in 20 ccs, i. e. 1/222 N. "

The above amounts of silver chromate formed at the first coagulation points have been plotted against the gelatine concentrations in Fig. 6. From this curve the amount of silver chromate at the precipitation point for a 0.8% gelatine solution is found to be about 0.017 gram in 20 ccs i. e. 0.0052 N silver chromate.

Therefore in a 0.8% gelatine gel, one would expect the silver chromate to be a precipitate when the two reacting solutions are each about 0.0052 N. This condition is very nearly satisfied between 0.6 and 0.75 cms from the top of the gel as can be seen from Table VI. In Fig. 7, the concentrations of silver nitrate and potassium chromate have been plotted against distances of various layers of the gel, and it is found from the curve that at a distance of about 0.69 cms from the top the two solutions are equivalent, each being 0.006 N. Thus in this layer 0.006 N silver chromate would be formed. One

would therefore expect this layer to be a precipitate, because it has been shown by actual experiment that 0.0052 N silver chromate when formed in 0.8% gelatine is a precipitate.

From Fig. 7 we also find that 0.0025 N. silver chromate would be formed at a distance of about 0.175 cm from the top of the gel. From Table IV, however, we find that 0.0084 gram (i. e. 0.0025 N.) of silver chromate when formed in 0.8% gelatine comes down as a precipitate only in presence of 0.01 gram of silver nitrate, but is perfectly peptised in presence of larger quantities

FIG. 7

of silver nitrate. From Table VI, we again find that there is a very large amount of silver nitrate present in that layer, in fact much larger than 0.01 gram per 20 ccs. Evidently then at that layer there will be a perfectly peptised sol. If we consider the layer of the gel say at 0.05 cm from the top, the amount of silver nitrate present in excess in that layer is enormously large, about 700 times the amount of potassium chromate. So one would expect precipitation in that layer.

From the above considerations, therefore, we clearly see that there will be layers of precipitate at distances of 0.05 and 0.7 cm from the top of the gel. There will also be a layer at a distance of 0.175 cm from the top of the gel in the neighbourhood of which, all the silver chromate will be in a stabilised or colloidal form. Other layers will be expected intermediately, near 0.4 cm from the top, depending on the particular concentration of silver nitrate that is capable of producing a precipitate with a certain concentration of silver chromate.

In the above calculations a static state of affairs has been assumed for a period of one hour. This assumption gets more and more justifiable as the

period decreases. There seems however every reason to suppose that there is no intrinsic change in the nature of the reaction, as the period, over which the diffusion process takes place, gets longer.

In an actual experiment, therefore, as the silver nitrate diffuses in, it meets a layer of potassium chromate and being itself in a very large concentration, forms a layer of precipitate. As it travels down in the gel, its concentration gets less and probably attains such a value that the amount of silver nitrate present in excess, is the amount just wanted for the peptisation of the amount of silver chromate formed in that layer. This layer is thus a peptised layer. Later on as the silver nitrate travels further in the gel, it, in all probability, meets the potassium chromate in equivalent concentration (or very nearly equivalent), and if the concentration has a certain value, the silver chromate formed in that layer comes down as a precipitate. It thus gives rise to a layer of precipitate. This process repeats itself as the silver nitrate diffuses onwards into the gel, and a series of alternately precipitated and peptised layers are thus obtained.

Summary

1. The stabilisation of silver chromate by gelatine and of lead chromate by agar-agar, have been studied. The above chromates were obtained by mixing solutions of the respective nitrates with a potassium chromate solution. The concentrations of the various reacting solutions, and of the stabilisers, were varied, one at a time, to study their respective influences on the stabilisation of the above mentioned substances.

2. By measuring their capacity, it has been possible to get a comparative measure of the extent to which the various resulting mixtures have been stabilised. For this purpose, the nephelometer devised by Kingslake, has been used with a slight modification.

3. To get reproducible results, it was found necessary to mix the above reacting solutions uniformly and simultaneously. An arrangement has been set up which meets the above purpose.

4. When gradually increasing amounts of silver chromate were formed, by the addition of a series of solutions of silver nitrate of gradually increasing concentrations, to a corresponding series of solutions of potassium chromate, the concentrations of each pair of the reacting solutions being exactly equivalent, it was found that the turbidities of the resulting mixtures varied in a periodic manner, although the amount of the stabiliser was constant throughout. There were two distinct zones at which the resulting mixtures showed the maximum turbidities.

5. The influence of the concentration of the stabilising solution, on these coagulation zones, has been studied. It was found that with increasing concentrations of the stabiliser, these zones become less and less prominent.

6. The influence of an excess of either Ag or CrO_4 ions on the stabilisation of silver chromate by gelatine has been studied quantitatively. It has been found that both the above ions have a distinct stabilising influence on silver chromate.

7. In the case of stabilisation of silver chromate by an excess of free Ag ions, a critical concentration was found; the Ag ions acted as a stabiliser, only when present in concentrations greater than this critical concentration. Free Ag ions, when present in concentrations below this critical value, had a distinct, though slight, coagulating influence.

8. The stabilisation of lead chromate by agar-agar has been studied. It has been found that the presence of an excess of free chromate ions greatly helps the peptisation of lead chromate by agar-agar, but lead ions do not seem to have any such effect.

9. It has been shown that lead chromate can adsorb chromate ions, but not lead ions. A colloidal solution of lead chromate has been prepared through the stabilising influence of chromate ions.

10. As a result of the foregoing experiments, it has been found that a solution of silver nitrate reacting with a potassium chromate solution, will form a turbid (precipitated) mixture, only when one of the following two conditions, is fulfilled:

(1) Unless very concentrated, if the two reacting solutions be equivalent, they will be precipitated only when the quantity of the silver chromate formed is a certain definite amount (which will be dependent on the concentration of the gelatine solution used). When the quantity of silver chromate is either greater or smaller than this amount a peptised solution will result.

(2) When one of the reacting solutions is used in excess, for a given weight of silver chromate, and a given gelatine concentration, precipitation will occur, only when a certain weight of one of the reacting substances is left in excess. If the amount of the substance left in excess, be greater or less than this quantity, a peptised sol instead of a precipitate will result.

11. The distribution of concentrations of a pair of silver nitrate and potassium chromate solutions of given concentrations, in a gelatine gel, has been calculated by using Fick's diffusion equation.

12. By correlating the values from the above calculations for the concentrations at different strata of the gelatine gel with the experimental observations, it has been shown that certain layers of the gel will contain Ag_2CrO_4 in a peptised form, whilst other layers will consist of precipitated silver chromate.

In conclusion the author wishes to express his thanks to Prof. Donnan, for his many valuable suggestions and for his kind interest in this work.

THE SYSTEM SODIUM SULPHATE-WATER: I. THE DENSITIES AND SPECIFIC VOLUMES OF AQUEOUS SOLUTIONS OF SODIUM SULPHATE BETWEEN 25 AND 40°, AND THE FICTIVE VOLUMES OF SODIUM SULPHATE IN SOLUTION

BY R. E. GIBSON

In a study of the effect of pressure on the equilibria between salts and their solutions a knowledge of the Fictive Volumes of the salts in solution is of the utmost importance. To determine the fictive volumes, that is to say the increase in volume which an infinitely large volume of the solution undergoes when one gram of the salt is added, it is necessary to know the specific volumes of solutions of the salt at various concentrations to as high a degree of accuracy as possible. Such data were not available in the case of sodium sulphate and it is the object of this paper to supply the need.

Experimental

The work was divided roughly into two parts.

First, the densities, and hence the specific volumes of solutions containing from 1 to 28 per cent of sodium sulphate were accurately determined at 25°. For solutions containing up to 21 per cent of Na_2SO_4 the density could be determined directly at that temperature but in the case of solutions of higher concentration the density was found at 30° and then converted to that at 25°.

Second, by means of a dilatometer the change in specific volume per degree between 25° and 40° was found for each solution. By combining these results it was possible to calculate the specific volume of any solution of sodium sulphate between 25 and 40°.

Density Determinations. The densities of the solutions were found by a pycnometer method. The pycnometers, thermostat tank, balance, and weights were those described by Hall,¹ and his technique and precautionary measures were observed throughout.

The temperature of the bath was checked frequently by a 10-junction copper-constantan thermel, one limb of which dipped into the thermostat near the pycnometer while the other was immersed in melting ice. The thermel was constructed by the author and was calibrated against the Standard 25-junction element of the Bureau of Standards with the kind assistance of Dr. W. P. White. The E. M. F. of the thermel was read with a Wolff potentiometer. The mean fluctuation of the bath was $\pm 0.005^\circ$. The standard cell of the potentiometer was calibrated at the Bureau of Standards.

Sodium sulphate. J. T. Baker's C. P. Analyzed crystalline sodium sulphate decahydrate was used. It was recrystallized from water three times, care being taken each time to free the crystals from adhering solution by suction. The purified crystals were then kept in a vacuum desiccator over

¹ Ralph E. Hall: J. Wash. Acad. Sci., 14, 167 (1924).

KOH until they were reduced to a fine anhydrous powder. Finally the powdered salt was heated in a platinum vessel to $400\text{--}500^\circ$ for six hours. The loss in weight of the Na_2SO_4 during this operation never exceeded 0.1 per cent.

Solutions. For each determination a fresh solution was prepared directly from salt and water. Here again Hall's method was used and at no time did any trouble arise from the formation of bubbles of air in the solution. When large amounts of the salt were required, however, the salt was weighed directly in the standard flask wherein the solution was prepared. This method proved more reliable than washing the salt into the flask from a separate weighing vessel.

Procedure. Before each experiment the pycnometers were washed out with a chromic acid solution and with distilled water and dried by a current of dried, filtered air. They were then immersed in distilled water, dried with a linen cloth, and suspended on the balance arms. After half an hour, when equilibrium was attained, the difference in weight was taken, double weighings being made in all cases. The constancy of the weight of the solution-pycnometer was comparable with the figures given in Hall's paper. The solution-pycnometer was then filled, immersed in the thermostat, adjusted and weighed as Hall describes. The weight of the solution was corrected for the temperature, pressure, and the humidity of the air in the balance case.

Experiments with pure water gave the volume of the solution-pycnometer and were performed at intervals throughout the work. The results are given in Table I. The volume of the pycnometer at 25° is 55.0365 milliliters and at 30.0° is 55.0448 milliliters.

TABLE I
Calibration of Pycnometer

	9	54.8068
	10	54.8068
30°	Average	54.8069

In order to avoid any errors due to elastic hysteresis in the glass, the experiments at 25° were all completed before those at 30° were undertaken.

Dilatometer Experiments. The dilatometer, used in the determination of the coefficients of expansion of the different solutions is shown in Fig. 1. It

consisted of a bulb, *A*, some 50 cc in capacity, to which was sealed a graduated capillary tube, *C*, whose internal diameter was about 1 mm. Liquid was introduced into the dilatometer through *C* by withdrawing the air at *B*. The stopcock *D*, was very carefully selected and gave no leakage trouble whatsoever.

The whole was then immersed in a large enclosed bath holding about 5 liters of water which was stirred vigorously. The bath was provided with an electrical heater and a cooling coil. By means of a variable resistance in series with the heater the temperature of the bath could be held within 0.1° of any point for any length of time. The temperature of the bath was read with the thermel described above. The position of the meniscus in the capillary was read with a lens, correct to 0.1 mm of the scale.

Procedure. After the dilatometer had been completely filled and was immersed in the bath at 25° , the stopcock, *D*, was opened and the liquid allowed to run very slowly down the capillary until the meniscus reached a certain definite zero mark. It was essential that the capillary should be absolutely clean and that no liquid should adhere to the upper portions of the capillary tube.

The stopcock was then closed and the whole was kept at 25° until equilibrium was attained, when the position of the meniscus was observed. The temperature was then raised slowly and readings were taken at intervals of 2.5° . In each case half an hour was allowed for the dilatometer to come into equilibrium with its surroundings. Owing to the limited length of the capillary the highest temperature reached was 37.5° , whereafter readings were taken with falling temperature down to 25° . If two readings at the same temperature differed by 0.2 mm., indicating hysteresis of the glass, leakage or formation of bubbles, the run was rejected. This was only necessary in one case.

A thermometer was suspended alongside the capillary and the air temperature was taken at the time of each reading. Hence a stem correction could be made

to bring the volume of the liquid in the capillary to the volume it would occupy at the temperature of the bath.

Calibration of the dilatometer. The graduated capillary tube, *C*, was calibrated by means of a weighed thread of mercury. The bore was very regular indeed, the maximum and minimum cross section areas being 1.120 and 1.116 mm² respectively. The mean cross section area of the capillary was taken as 1.118 mm². The capillary was graduated in millimeters. The volume of the dilatometer at 25° was determined by weighing its water content at that temperature. It was 47.394 milliliters.

FIG. 1
Diagram of dilatom-
eter

To determine the correction to be added for the expansion of the glass, i. e. to convert *apparent* to *real* expansion, several runs were made with pure water whose coefficient of expansion was taken from the Smithsonian tables.

Let $\Delta h''$ represent the observed rise of the water in the capillary for a temperature rise of Δt° and let Δv represent the increase in volume of 1 gram of water for the same change of temperature. Then if M is the mass of water in the dilatometer, $M\Delta v$ is the real expansion.

Also if a is the area of the cross section of the capillary and $\Delta h'$ is the rise in the level of the water which should occur, were there no expansion of the glass,

$$M\Delta v/a = \Delta h'$$

The correction $(\Delta h' - \Delta h'')$, was found for various temperatures and the curve of $(\Delta h' - \Delta h'')$ against temperature was plotted. The curve was accurately represented by the equation

$$(\Delta h' - \Delta h'') = 1.28 (t - 25) \quad (A)$$

Results

The results of the density determinations made at 25 and 30° are given in Table II. The weighings are corrected to vacuum. In Table III the first steps in rounding off the results to even concentrations are given. All the densities are reduced to 25° and in column 2 the corrections necessary to bring the check determinations to the same percentage have been made. Here the experimental consistency may be studied.

*4th and 5th values were taken from work in which a larger pycnometer was used.

Empirical equations giving the relation between density and concentration in solutions. In order to find the values of the densities of solutions of even concentrations, as are given in Table IV, it was expedient to find a simple equation which would represent density as a function of concentration as accurately as possible. It is usual to employ a power series for this purpose and such may be derived from a difference table or by the solution of simultaneous equations, but the labor involved in the derivation of a cubic or biquadratic is very considerable.

Moreover, when differentiated, as is necessary in the computation of fictive volumes, these power series do not simplify at all. Hence another type of equation was sought.

It was found that the equation

$$\log \rho = ax_2 + b \quad (\text{B})$$

where ρ is the density, x_2 is the percentage of Na_2SO_4 and a and b are constants, fits the observations as well as a cubic equation. In Table III are the calculated values obtained from Equation 1, a logarithmic one, and Equation 2, a cubic one. In columns 5 and 7 the differences between the observed and calculated values are given. These differences, when plotted against the concentration, gave the deviation curves.

The equations from which the final calculations were made were:

$$\text{Eqn. (1) } \log \rho = 0.00381823 x_2 - 0.0011563$$

$$\text{Eqn. (2) } \rho = 0.997077 + 0.00893498 x_2 + 0.00002094 x_2^2 + 0.0000006075 x_2^3$$

$$\text{Eqn. (3) } \log \rho = 0.0038256 x_2 - 0.0012570$$

Equation 3 was derived for the range of concentration, 10 to 28 per cent, so that a check on the calculations at higher concentrations might be made. By combining each of these equations with the appropriate deviation curve we calculated the densities corresponding to even percentages of Na_2SO_4 and these are shown together in Table IV. In column 5 the mean of the three sets of values is given and a weighted mean is shown in column 6. When the difficulties of drawing an accurate deviation curve are considered, it will be seen that the agreement among the three interpolations is very satisfactory. The specific volumes of solutions of Na_2SO_4 at 25° are given in column 7.

TABLE IV

Final values of densities and specific volumes of solutions of Na_2SO_4

Results of the Dilatometer Experiments

From experiments the following quantities were obtained directly:

R_0 = the height of the meniscus in the capillary at 25° .

R = height of the meniscus (corrected for stem temperature) at t° .

t = the temperature of the bath.

It was found most convenient to work with $\Delta t = t - 25$, so this quantity will be used throughout.

$R - R_0$ is a function of the apparent expansion and was converted to Δh , a function of the real expansion, by adding the appropriate correction from Equation A.

Then, if a be the cross section of the capillary, V_{25} , the volume of the dilatometer at 25° and $\Delta V/V_{25}$ the relative change in volume or the increase in volume which 1 cc (at 25°) of the solution undergoes when its temperature is raised Δt° ,

$$\Delta V/V_{25} = a\Delta h/V_{25}.$$

$\Delta V/V_{25}$, was used in all the intermediate steps as it is quite independent of the specific volume of the solutions at 25° and so the slight corrections to bring the observed results to those for even percentages of salt could readily be made by straight interpolation. For each solution observations were taken at six temperatures and quadratic equations were obtained to represent $\Delta V/V_{25}$ as a function of Δt by the method of least squares.

The equations were of the form

$$\Delta V/V_{25} = a' + b't + c't^2 \quad (C)$$

In Table V the results on the relative changes of volume of solutions of Na_2SO_4 are given in a complete form. For each concentration the observed volume changes are shown and alongside them are written the volume changes calculated from the quadratic equation. The column marked "Diff." contains the difference between the observed and calculated values and demonstrates how closely the equations fit. The coefficients a' , b' , and c' are given at the head of each column.

The quantity sought, however, was Δv , the increase in the *specific* volume for a given rise of temperature, or the expansion per gram of solution.

TABLE VI
Calculation of coefficients b and c

x_2	$b' \times 10^3$	$c' \times 10^3$	v (at 25°)	$b \times 10^3$	$c \times 10^3$
0	0.2599	0.00435	1.00293	0.2607	0.00436
1	0.2740	0.00420	0.99394	0.2723	0.00417

TABLE VII

The values of Δv , the increments in volume to be added to the specific volume at 25° to obtain the specific volume at t° .

Concentration per cent	$10^3 \Delta v$			
	$t = 25^\circ$	$t = 30^\circ$	$t = 35^\circ$	$t = 40^\circ$
0	0	1.413	3.043	4.892
1.0	0	1.466	3.140	5.023
5.0	0	1.620	3.401	5.342
10.0	0	1.727	3.571	5.536
15.0	0	1.774	3.634	5.581
20.0	0	1.771	3.611	5.519
25.0	0	1.737	3.522	5.356
28.0	0	1.705	3.449	5.136

It is obvious that $\Delta v/v_{25} = \Delta V/V_{25}$, or $\Delta v = v_{25} \Delta V/V_{25}$, where v_{25} is the specific volume of the solution in question at 25° .

$$\text{Hence if } \Delta v = a + bt + ct^2 \quad (\text{D})$$

$$a = a'v_{25}, b = b'v_{25}, c = c'v_{25}.$$

The calculation of the coefficients, b and c , is given in Table VI. This enables us at once to compute the specific volume of any solution of Na_2SO_4 between 25° and 40° .

In Table VII are given the values of Δv , the amount to be added to the specific volume at 25° to obtain the specific volume at t° .

FIG. 2

The expansibilities of sodium sulphate solutions at various concentrations and temperatures.

By differentiating the equation (D)

$$v = a + bt + ct^2$$

$$\text{we obtain } dv/dt = b + 2ct \quad (\text{E})$$

which is the coefficient of expansion of 1 gram of solution.

In Fig. 2 the values of $(b + 2ct)$ at 25° , 30° , 35° , and 40° are plotted against the percentage of Na_2SO_4 .

Calculations of the Fictive Volumes of Sodium Sulphate in Solution at 25°

Following the practice employed in the foregoing, we decided first to calculate the fictive volumes of the salt in solution at 25° and thereafter to derive the increments in fictive volume with temperature from the expansion equations.

Consider a system of two components, designated by the subscripts 1 and 2. Let m_1 and m_2 be the masses of the components present in a total volume V of the system. Then the fictive volume, v_1 , of component (1) is given by the equation

$$v_1 = \left(\frac{\partial V}{\partial m_1} \right)_{m_2, p, T}.$$

If $x_1 = \frac{100 m_1}{m_1 + m_2}$ and $x_2 = \frac{100 m_2}{m_1 + m_2}$, the percentages of the components pre-

sent are used, it may easily be shown that

$$v_2 = x_1 \frac{dv}{dx_2} + v, \quad v_1 = x_2 \frac{dv}{dx_1} + v. \quad (\text{F})$$

where v is the specific volume of the system. In the present case we have considered Na_2SO_4 as component (2) and H_2O as component (1). It may be emphasized, however, that similar results would have been obtained had the components been $\text{Na}_2\text{SO}_4 \cdot n\text{H}_2\text{O}$ and H_2O .

FIG. 3

The fictive expansibilities of sodium sulphate in solution at various concentrations and temperatures.

From the formula connecting density and concentration we have:

$$\log \rho = ax_2 + b$$

$$\text{i. e. } \log (1/v) = ax_2 + b$$

$$\text{Hence } dv/dx_2 = -av \times 2.303 \quad (\text{G})$$

Thus a first approximation to the fictive volume of a salt in solution may be given by the simple formula

$$v_2 = v (1 - 2.303 ax_1) \quad (\text{H})$$

To obtain the highest accuracy from the observations, however, it is necessary to correct dv/dx_2 by a term from the deviation curve. From the deviation curves used for the interpolations described above a correction for $d\rho/dx_2$ was obtained graphically. This, on being multiplied by $-v^2$, gave the term to be added to $-av \times 2.303$ to obtain the best value of dv/dx_2 .

In order to check the values obtained by this method the cubic equation was also differentiated and a corrected value of dv/dx_2 obtained with the aid of the deviation curve.

The results are given in Table VIII.

TABLE VIII
Fictive volumes of Na_2SO_4 in solution at 25°

x_2	v_2 (From Eqn. 4)	v_2 (From Eqn. 2)	v_2 (From Eqn. 3)	v_2 Final values (Weighted Mean)
0				(0.0860)
1.0	0.1140	0.1147		0.1144
2.0	0.1292	0.1287		0.1288
3.0	0.1392	0.1396		0.1394
5.0	0.1570	0.1581		0.1578
10.0	0.1942	0.1942	0.1937	0.1940
15.0	0.2223	0.2227	0.2227	0.2226
20.0	0.2476	0.2478	0.2479	0.2478
25.0	0.2699	0.2694	0.2702	0.2698
28.0	0.2826	0.2820	0.2827	0.2824
30.0				(0.2906)

In columns 2 and 4 are the values calculated with the help of Equations 1 and 3 and their deviation curves, while column 3 gives the figures from the cubic equation 2 and its deviation curve. The weighted mean is printed in column 5. The values in parentheses are the results of extrapolations using Equation K.

The fictive volumes at 25° are represented as a function of concentration with great exactness by the equation

$$\log (v_2 - 0.0860) = 0.58177 \log x_2 + \bar{2}.4518 \quad (\text{K})$$

The agreement between observed and calculated values is illustrated in Table IX.

TABLE IX

Comparison of the values of fictive volumes of Na_2SO_4 in solution at 25° with those calculated from Equation K.

x_2	v_2 (From observations)	v_2 (Calculated from Eqn. K)	Diff. $\times 10^4$
1.0	0.1144	0.1143	+1
2.0	0.1288	0.1284	+4
3.0	0.1394	0.1396	-2
5.0	0.1578	0.1582	-4
10.0	0.1940	0.1940	0
15.0	0.2226	0.2228	-2
20.0	0.2478	0.2477	+1
25.0	0.2698	0.2701	-3
28.0	0.2824	0.2826	-2

A glance at Equation K will show that $0.0860 = (v_2)_0$, the fictive volume of the salt at zero concentration. Thus if we write $\Delta v_2 = [v_2 - (v_2)_0]$ we can convert the equation to the form

$$\Delta v_2 = 0.0283 x_2^{0.58177} \quad (L)$$

Although the specific volumes are given confidently to at least 1 part per 100,000, the fictive volumes calculated therefrom can only be written with an accuracy of 0.5 per cent. This is due to the fact that the slopes of the deviation curves influence the final values of the fictive volumes by about 5 per cent and in these deviation curve slopes the uncertainties arise. It should be emphasized that to obtain an accuracy of 1 to 0.1 per cent in the values of the fictive volumes, the specific volumes must be known to 0.001 per cent or closer.

Fictive Volumes and Fictive Expansibilities at Various Temperatures

The fictive volumes at 25° and the coefficients of expansion of the solutions having been obtained, it was a comparatively simple matter to pass to the fictive volumes at other temperatures.

If $(v_2)_{25}$ be the fictive volume at 25° and $(v)_{25}$ be the specific volume at that temperature,

then $(v)_t = (v)_{25} + bt + ct^2$, where b and c are the constants of Eqn. D.

Now $(v_2)_t = x_1 d(v)_t/dx_2 + (v)_t$

$$= x_1 d/dx_2 [(v)_{25} + bt + ct^2] + (v)_{25} + bt + ct^2$$

$$= (v_2)_{25} + t(b + x_1 db/dx_2) + t^2(c + x_1 dc/dx_2).$$

$$\text{Or } (v_2)_t = (v_2)_{25} + Bt + Ct^2 \quad (M)$$

where $B = b + x_1 db/dx_2$ and $C = c + x_1 dc/dx_2$.

The coefficients, B and C , are readily found from the slopes of the curves of b and c plotted against x_2 at 25°.

The values of the fictive volumes at 25, 30, 35, and 40° are given in Table X.

TABLE X

Fictive volumes of Na_2SO_4 in solution at different temperatures.

x_2	Fictive volumes of Na_2SO_4			
	$t = 25^\circ$	$t = 30^\circ$	$t = 35^\circ$	$t = 40^\circ$
0	0.0860			
1	0.1144	0.1208	0.1262	0.1306
5	0.1578	0.1622	0.1659	0.1689
10	0.1940	0.1970	0.1995	0.2015
15	0.2226	0.2247	0.2264	0.2279
20	0.2478	0.2492	0.2504	0.2514
25	0.2698	0.2708	0.2717	0.2724
28	0.2824	0.2833	0.2840	0.2847

By differentiation of Equation M with respect to temperature, keeping

x_1 constant, we have $\left(\frac{\partial v_2}{\partial t}\right)_{x_1} = B + 2Ct$.

Hence α_2 , the fictive expansibility of Na_2SO_4 in solution is given by

$$\alpha_2 = \left(\frac{\partial v_2}{\partial t} \right)_{x_2} = B + 2Ct.$$

In Fig. 3 the curves of α_2 , as a function of x_2 , are plotted for 25, 30, 35 and 40°

It may easily be shown that the fictive volume of the water, $\frac{\partial V}{\partial m_1} = v_1$, is given by the equation

$$v_1 = v - x_2 dv/dx_2$$

A mean of the three values of dv/dx_2 used for the calculations of the fictive volumes of the Na_2SO_4 was used for this computation of v_1 and the results are given in Table XI.

TABLE XI

Calculation of v_1 (fictive volume of H_2O in Na_2SO_4 solutions) at 25°

Discussion of Results

The immediate purpose of this paper is the provision of thermodynamic data, so that very little discussion of the results will be attempted at this stage but attention may be drawn to the following points.

As would be expected, the specific volumes of the solutions and hence the fictive volumes show no sudden changes at 32.5°, the transition point of the decahydrate to the anhydrous salt. There are, however, strong indications that the salt is very highly hydrated in the dilute solutions at the lower temperatures and that as temperature and concentration increase this hydration gradually diminishes. We wish to use the term hydration, or in general, solvation, in a very broad sense and would define it as follows.

If a molecule or ion of a salt in a solution tends to alter its environment in such a way that the molecules of the solvent are more closely packed around the salt than in the pure solvent the salt is solvated in solution. In other words, if we introduce into water one molecule of a salt which is hydrated in solution, the molecule will hold to itself by attractive forces varying in intensity, n molecules of water.¹ The nature of the attracting forces and the magnitude of n are purposely left indefinite.

¹ A. Eucken: "Fundamentals of Physical Chemistry." (Translated by Jette and LaMer.) p. 245 (1925).

The first indications of a high degree of hydration of the sodium sulphate were found in the very low values of the fictive volume at low concentrations and the rapid rise in fictive volume with increase of concentration. Although the specific volume of Na_2SO_4 in the solid state is 0.375, the fictive volume at zero concentration is only 0.086 while the fictive volume in a 25 per cent solution is 0.27.

On the other hand, in the case of sodium chloride where the specific volume in the solid state is 0.462, the fictive volumes of the salt in solutions containing 0.5 and 25 per cent of NaCl are 0.30 and 0.40 respectively.¹

Perhaps the most striking evidence of the apparent hydration of the salt in the solution is obtained from the curves for the fictive expansibilities in Fig. 3. In this diagram the fictive expansibilities of the Na_2SO_4 , $\partial v_2/\partial t = \alpha_2$ are plotted against x_2 for four different temperatures. From the relative positions of the curves it will be seen that α_2 diminishes as the temperature is raised. Furthermore all the curves appear to converge on a value of α_2 which is of the order of 0.0001.

From the results of Jaeger² on the densities of molten salts we find that dv/dt for liquid Na_2SO_4 at 900° is 0.00023. This value is undoubtedly much higher than dv/dt for the undercooled liquid at 25° . In fact no large error would be made by supposing that at 25° dv/dt is of the order of 0.0001. We might, therefore, state with some degree of certainty that at higher temperatures and concentrations the fictive expansibility of Na_2SO_4 in solution tends to the value of the expansibility of the pure liquefied Na_2SO_4 .

How are we to account for the very large values of the fictive expansibilities of Na_2SO_4 at the lower temperatures and concentrations? An explanation is forthcoming if we consider the fictive expansibility as the result of two factors: (1) the thermal expansion of the pure liquefied solute, and (2) the expansion due to the dissociation of the hydrate complexes as the temperature rises. If the salt is highly hydrated at the low temperatures and concentrations, then, as the temperature is raised, dehydration takes place and is made apparent through a large value of the fictive expansibility of the salt. As the solution becomes more concentrated, the salt is less hydrated and consequently the amount of dehydration per degree rise of temperature falls off and α_2 diminishes. Finally, when the concentration and temperature are high enough, we can assume that we are dealing with the almost anhydrous salt and a fairly constant value of α_2 is obtained.

In the above discussion we have assumed that factor (1) varies very slightly with dilution. Although this is at present not capable of proof, we can see from the flatness of the 40° curve that it is an approximation to the truth.

Thus it is the very rapid diminution in α_2 from its relatively large value at zero concentration and at 25° as temperature and concentration are increased which leads us to confirm the supposition that Na_2SO_4 is highly

¹ Unpublished calculations from the data on the densities of NaCl by Hall: *op. cit.*

² F. M. Jaeger: *Z. anorg. allgem. Chem.*, 101, 182 (1917).

hydrated in aqueous solution at low temperatures and concentrations and that this hydration decreases as temperature and concentration are increased.

The complex nature of water itself and the lack of further data prevent us from proceeding further with the discussion at present.

In conclusion the author wishes to take the opportunity of expressing his gratitude to Dr. L. H. Adams for his advice and criticism which have been frequently sought and freely given during the prosecution of the work.

Summary

The densities and specific volumes of solutions of sodium sulphate at 25° and over a range of concentration from 0 to 28 per cent have been determined with an accuracy of 5 to 10 parts per million. The thermal expansibilities have been determined for the same solutions between 25° and 40° with the same accuracy. From these data the fictive volumes of sodium sulphate and water in solutions of sodium sulphate have been calculated.

AQUEOUS SOLUTIONS OF SODIUM SILICATES VI HETEROGENEOUS EQUILIBRIA SYSTEM: $\text{Na}_2\text{O}:\text{SiO}_2:\text{H}_2\text{O}$, AT 25°C

BY R. W. HARMAN

Introduction

There seems to be no doubt about the existence of the definite crystalline salt, sodium metasilicate, Na_2SiO_3 . This series of investigations, comprising conductivity, transport numbers, hydroxyl ion concentration, sodium ion concentration, silicate ion concentration, and total osmotic activity measurements, on solutions of varying ratio $\text{Na}_2\text{O}:\text{SiO}_2$, indicates that Na_2SiO_3 exists as such in solution at 25°C and that in all probability a definite salt of the composition $\text{Na}_2\text{O}:2\text{SiO}_2$, the evidence already obtained pointing to NaHSiO_3 , also exists in solution at this temperature,

Some indication of what salts do exist and are stable in solution, may be gained by means of a phase rule investigation of the ternary system $\text{Na}_2\text{O}:\text{SiO}_2:\text{H}_2\text{O}$ at 25°C . No such investigation is found in the literature; but some work, mostly from the Geophysical Laboratory, Washington, has been done in connection with the problem of alkali silicate melts at high temperatures.

Niggli,¹ by the hydrothermal quenching method, investigated the system $\text{R}_2\text{CO}_3:\text{SiO}_2$ (where $\text{R} = \text{Na}, \text{K}, \text{Li}$) in melts at temperatures ranging between $800^\circ\text{--}1000^\circ\text{C}$. He concluded that the following equilibria existed:—

- (1) $\text{K}_2\text{CO}_3 + \text{K}_2\text{Si}_2\text{O}_5 \rightleftharpoons 2\text{K}_2\text{SiO}_3 + \text{CO}_2$
- (2) $\text{Na}_2\text{CO}_3 + \text{Na}_2\text{SiO}_3 \rightleftharpoons \text{Na}_4\text{SiO}_4 + \text{CO}_2$
- (3) $2\text{Li}_2\text{CO}_3 + \text{Li}_4\text{SiO}_4 \rightleftharpoons \text{Li}_3\text{SiO}_5 + 2\text{CO}_2$ (presumably)

In each system, the compound containing more silica is the poorest in silica which can be prepared pure, at the particular temperature, merely by melting together carbonate and SiO_2 . Thus K_2SiO_3 or Na_4SiO_4 or Li_3SiO_5 cannot be prepared in the pure state from carbonate and silica at temperatures about 1000°C ; the compounds $\text{K}_2\text{Si}_2\text{O}_5$, Na_2SiO_3 , Li_4SiO_4 containing more silica can readily be obtained.

Both Niggli and Wallace² failed to obtain a definite salt richer in silica than the metasilicate. Morey³ by the hydrothermal quenching method, investigated the system alkali silicate:water at temperatures $300^\circ\text{--}400^\circ\text{C}$ and higher. He obtained the following crystalline products:

- (1) $\text{K}_2\text{O}.\text{H}_2\text{O}.4\text{SiO}_2$ or KHSi_2O_5 , at $200^\circ\text{--}450^\circ\text{C}$.
- (2) $\text{K}_2\text{O}.2\text{SiO}_2$ or $\text{K}_2\text{Si}_2\text{O}_5$, at 500°C .
- (3) $\text{Na}_2\text{O}.2\text{SiO}_2$ or $\text{Na}_2\text{Si}_2\text{O}_5$, above 400°C .
- (4) $\text{Na}_2\text{O}.\text{SiO}_2$ or Na_2SiO_3 , above 400°C .

¹ J. Am. Chem. Soc., **35**, 1693 (1913).

² Z. anorg. Chem., **63**, 1 (1909).

³ J. Am. Chem. Soc., **36**, 215 (1914).

He observed that KHSi_2O_5 and $\text{Na}_2\text{Si}_2\text{O}_5$ were not readily affected by water, while $\text{K}_2\text{Si}_2\text{O}_5$ and Na_2SiO_3 were decomposed very rapidly. Morey's attempts to prepare the compound NaHSi_2O_5 , analogous to KHSi_2O_5 , were unsuccessful, as were also his efforts to obtain crystals of K_2SiO_3 . In this connection it is interesting to note that Niggli found at higher temperatures in the systems $\text{K}_2\text{O}:\text{SiO}_2:\text{CO}_2$ and $\text{Na}_2\text{O}:\text{SiO}_2:\text{CO}_2$ that the stable alkali silicates were $\text{K}_2\text{Si}_2\text{O}_5$ and K_2SiO_3 , and Na_2SiO_3 and Na_4SiO_4 , increase in temperature in both cases favouring the second form. It seems therefore that in the soda system at lower temperatures $\text{Na}_2\text{Si}_2\text{O}_5$ is stable and that increase of temperature favours first Na_2SiO_3 and then presumably¹ Na_4SiO_4 .

The ease with which the disilicates of sodium and potassium can be formed hydrothermally is in striking contrast to the rarity of the occurrence of minerals which can, with any degree of certainty, be considered essentially as disilicates i. e. as salts of the hypothetical acid $\text{H}_2\text{Si}_2\text{O}_5$. The only mineral that is unquestionably a disilicate is *rivaite* $(\text{Ca.Na})\text{Si}_2\text{O}_5$, described by Zambonini, and which occurs very sparingly among the ejected rocks at Vesuvius. Practically all the other minerals cited in the literature as disilicates contain alumina and may more rationally be regarded as derivatives of aluminosilicic acids.

It is most interesting to note that Morey did not obtain evidence of the existence of any of the many crystalline hydrates of Na_2SiO_3 described by previous workers.

Morey² has investigated the system $\text{H}_2\text{O}:\text{K}_2\text{SiO}_3:\text{SiO}_2$ at temperatures ranging from 200° – 1000°C . He established the existence of:

- (1) KHSi_2O_5 or $\text{K}_2\text{O}.\text{H}_2\text{O}.2\text{SiO}_2$, decomposed by H_2O below 420°C .
- (2) $\text{K}_2\text{Si}_2\text{O}_5$ or $\text{K}_4\text{O}.2\text{SiO}_2$.
- (3) $\text{K}_2\text{Si}_2\text{O}_5.\text{H}_2\text{O}$ or $\text{K}_2\text{O}.\text{H}_2\text{O}.2\text{SiO}_2$, rapidly decomposed by water at all temperatures.
- (4) K_2SiO_3 or $\text{K}_2\text{O}.\text{SiO}_2$, the stable solid phase in the binary system $\text{K}_2\text{SiO}_3:\text{H}_2\text{O}$ from 010° – 960°C , obtained in fairly pure condition by crystallising a metasilicate glass at high temperature.
- (5) $\text{K}_2\text{SiO}_3.0.5\text{H}_2\text{O}$ or $\text{K}_2\text{O}.0.5\text{H}_2\text{O}.\text{SiO}_2$, stable from 370° – 610°C .
- (6) $\text{K}_2\text{SiO}_3.\text{H}_2\text{O}$ or $\text{K}_2\text{O}.\text{H}_2\text{O}.\text{SiO}_2$, decomposed by water at temperatures below 200°C .

In a later paper Morey³ discusses the solubility and decomposition by water of glass and ceramic wares from the point of view of the phase rule, and brings out the distinction between compounds soluble in water and compounds decomposed by water, his observations being based on his already quoted work on the system $\text{K}_2\text{SiO}_3:\text{SiO}_2:\text{H}_2\text{O}$ at temperatures between 200° – 1000°C . He concludes that K_2SiO_3 at 285°C has a true solubility in water represented by the endpoint of the saturation curve on the $\text{K}_2\text{SiO}_3:\text{H}_2\text{O}$ side of the diagram, but is decomposed by water at about 180°C , the actual solid phase be-

¹ Zambonini: Atti Accad. Sci. Napoli, 12, No. 12, p. 16 (1912).

² J. Am. Chem. Soc., 39, 1174 (1917).

³ J. Soc. Glass Technology, 6, 20 (1922).

ing $\text{K}_2\text{SiO}_3 \cdot \text{H}_2\text{O}$. From the fact that the tie-line $\text{H}_2\text{O}:\text{K}_2\text{SiO}_3$ cuts the saturation curve of $\text{K}_2\text{SiO}_3 \cdot \text{H}_2\text{O}$, it follows that this compound also has a true solubility in water at 285°C , but is decomposed by water at 200°C . Morey did not follow the system to lower temperatures, but it is possible, from the general shape of all the stability fields, that at ordinary temperatures true equilibrium in any mixture of $\text{K}_2\text{O}:\text{SiO}_2:\text{H}_2\text{O}$ would mean a solution containing a vanishingly small amount of SiO_2 , the actual amount depending on the amount of K_2O present, in equilibrium with a solid crystalline phase of pure SiO_2 or a crystalline compound of SiO_2 and H_2O , if any such exists.

Morey and Bowen¹ studied the binary system $\text{Na}_2\text{SiO}_3:\text{SiO}_2$ in melts at temperatures round about 1000°C and obtained evidence of only two stable crystalline compounds.

- (1) Na_2SiO_3 or $\text{Na}_2\text{O} \cdot \text{SiO}_2$.
- (2) $\text{Na}_2\text{Si}_2\text{O}_5$ or $\text{Na}_2\text{O} \cdot 2\text{SiO}_2$.

but found no solid solutions of SiO_2 in these salts as Wallace had suggested.

Thus a considerable amount of work has been done on the simple alkali silicate system, but all at high temperatures, ranging from 400° – 1000°C , and by the hydrothermal quenching method, under which conditions Morey has established the stability of only two definite compounds, viz., $\text{Na}_2\text{O} \cdot \text{SiO}_2$ and $\text{Na}_2\text{O} \cdot 2\text{SiO}_2$. From Niggli's work there seems a possibility also of the existence of $2\text{Na}_2\text{O} \cdot \text{SiO}_2$ at high temperatures.

No work at all has been done in the wet way at ordinary temperatures, and so it was hoped that an investigation of the ternary system $\text{Na}_2\text{O} \cdot \text{H}_2\text{O}$ at 25°C would indicate if any sodium silicates are stable in solution at this temperature, and what, if any, is the possible number and constitution of their hydrates.

Experimental

The method of residues was employed. The materials used were:

- (1) Na_2SiO_3 prepared as described in Part I.²
- (2) a powder of composition $\text{Na}_2\text{O} \cdot 2\text{SiO}_2$.
- (3) a powder of composition $\text{Na}_2\text{O} \cdot 3\text{SiO}_2$.
- (4) caustic soda.
- (5) commercial solutions, of ratios varying from 1:2 to 1:5.

By using mixtures of the above materials it was possible to investigate nearly the whole system except that part towards the $\text{H}_2\text{O}:\text{SiO}_2$ side of the component triangle; but here another difficulty, probably insurmountable, arose, so that this part of the system is still incomplete. Nor does it seem possible to complete it at present, as will be shown later.

The mixtures of solid and water, or solution, were stirred vigorously in hard glass vessels immersed in a water thermostat kept at 25°C . The stirrer was fixed in through a mercury seal to exclude the CO_2 of the atmosphere, which at this temperature has a considerable effect on the equilibrium. It is unlikely that the mixtures have much effect on the glass vessel used, at this low

¹ J. Phys. Chem., **28**, 1167 (1924).

² J. Phys. Chem., **29**, 1155 (1925).

temperature. Even so, the effect would be merely to increase the alkali and silica, the other components of the glass introducing merely a negligible impurity. However, no noticeable effect on the glass vessels used was observed.

The mixtures were stirred continuously for over a week, in most cases from 8-14 days, depending on their viscosity, after which time the solution and the wet residues were analysed by the method already described in the paper on transport numbers.

The first difficulty encountered was that of obtaining some of the solution free from residue on account of its great viscosity.

Solutions of Na_2SiO_3 , and mixtures of Na_2SiO_3 , NaOH and H_2O were quite viscous, but not too viscous to be filtered so that a little of the clear solution could be obtained by filtering with the water pump. But in that part of the system lying between $\text{Na}_2\text{SiO}_3\cdot\text{H}_2\text{O}$ and the $\text{H}_2\text{O}:\text{SiO}_2$ side of the triangle, with increasing amounts of SiO_2 the viscosity became so great that all filtering methods were quite impossible. These very viscous solutions were allowed to stand in the thermostat after stirring continuously for nearly two weeks, and then the clearest portion, in most cases the top, but in some cases the bottom part, was centrifuged for a couple of days. In this way a solution almost clear but still a little cloudy, was obtained for analysis. Of course, the obtaining of the wet residue for analysis gave no difficulty. Still not much residue was obtainable in these viscous solutions, because, if too much solid remained undissolved, the whole formed a plastic mass like putty; therefore the amounts were so chosen as to leave some residue but not too much, and this being wet with the very viscous solution, often brought the two points closer together on the diagram than is desirable for accuracy.

By this means the system was investigated between the ratios $\text{Na}_2\text{O}:\text{SiO}_2$ 1:1 to 1:3, but it was felt that towards the ratio 1:3 the method was getting very doubtful. When solutions beyond the ratio 1:3 were attempted a new difficulty was encountered besides the viscosity. This was the fact that such an extremely viscous solution, when left to stand after stirring, set to what presumably was a gel. In fact, the mixture had most of the properties of silica gel—it was not sticky as all the other solutions were; it could be moulded into a ball, which was elastic, but which when placed on the bench slowly spread out. This not only made further experiments impracticable on this part of the system, but also cast doubt on the validity of the application of this method of investigation. This will be discussed later.

Results

The results are given in Table I. The method of analysis outlined in the paper on transport numbers¹ was closely followed.

¹ Harman: J. Phys. Chem., 30, 359 (1926).

TABLE I
Analyses of Solutions and Residues

Solution			Residue		
Na ₂ O	SiO ₂	H ₂ O	Na ₂ O	SiO ₂	H ₂ O

53.45	—	46.55	NaOH.1H ₂ O

Discussion of Results

It can be seen from Fig. 1 that there are only two types of solid phase:

(1) Na₂SiO₃ and its hydrates

(2) Na₂O.2SiO₂.9H₂O.

There is certainly at 25° C no compound richer in silica than the metasilicate. Both Jordis and Vesterberg (see below) made experiments with silicate solutions containing a great excess of alkali, as much as 14 Na₂O.SiO₂, but obtained no crystals richer in alkali than the metasilicate. Also, in view of the very colloidal nature of the mixtures obtained in this investigation above ratio 1:3, there is almost certainly no salt richer in silica than Na₂O. SiO₂.

Considering first the metasilicate and its hydrates we have:—

(1) Na₂SiO₃ anhydrous, enclosed by the saturation curve GH and the tie-lines from GH converging on D, on the Na₂O-SiO₂ side of the component triangle.

(2) Na₂SiO₃.2.5H₂O, enclosed by the saturation curve HI and the tie-lines converging on C, the point C representing almost exactly Na₂O.SiO₂.-2.5H₂O.

(3) $\text{Na}_2\text{SiO}_3 \cdot 6\text{H}_2\text{O}$, defined by the curve IJ and the point B.

(4) $\text{Na}_2\text{SiO}_3 \cdot 9\text{H}_2\text{O}$, enclosed by the saturation curve JKL and the tie-lines converging on A. The tie-line from A to the H_2O apex cuts this saturation curve of $\text{Na}_2\text{SiO}_3 \cdot 9\text{H}_2\text{O}$ and so this hydrate is stable in solution, i. e. has a true solubility in water.

FIG. 1

The tie-lines from B and C to the water apex do not cut the saturation curves of $\text{Na}_2\text{SiO}_3 \cdot 6\text{H}_2\text{O}$ and $\text{Na}_2\text{SiO}_3 \cdot 2.5\text{H}_2\text{O}$, hence these hydrates are decomposed by water. Therefore the only hydrate expected to crystallise from solution of ratio 1:1 would be the nona-hydrate, and this has actually been found true in the present investigation. Large well-defined crystals of $\text{Na}_2\text{SiO}_3 \cdot 9\text{H}_2\text{O}$ have also been obtained from a solution of ratio 2:1 and concentration $2 N_w$, without the addition of alcohol or without seeding. The other two hydrates are stable in more alkaline solution and may be prepared therefrom.¹

In connection with these hydrates there is rather a voluminous literature, as many authors have described crystals of sodium metasilicate, obtained from aqueous and alcoholic alkaline silicate solutions at ordinary temperatures, but the observations recorded are not at all concordant. Thus Petersen² described a monoclinic crystalline $\text{Na}_2\text{SiO}_3 \cdot 6\text{H}_2\text{O}$; Fritzsche³ described in detail triclinic crystals containing $6\text{H}_2\text{O}$; Yorke⁴ reports 7 aq.; several observers

² Ber., 5, 4c9 (1872).

³ Pogg. Ann., 43, 135 (1838).

⁴ Phil. Trans., 147, 533 (1857).

have reported 8 aq., including von Ammon¹ who described the monoclinic crystals he obtained; Jordis² found 6, 7, 8, 9, 10, 11, 12 H₂O; Vesterberg³ found 9 aq. and from dehydration experiments concluded that hydrates containing 6 and 3 aq. respectively also exist; Erdenbrecher⁴ obtained hydrates 9, 6 and 4 aq. respectively by crystallisation from an alkaline solution, increasing amounts of Na₂O in the ratio giving the lower hydrates; Morey⁵ in his investigations at high temperatures found none of these hydrates. This question of the hydrates can now be considered definitely settled, i. e. there are three hydrates, containing 9, 6 and 2.5 H₂O respectively.

The saturation curve from L onwards cannot be said to have the same definite accuracy as from F to L, on account of the experimental difficulties encountered. However, it is definite enough to indicate that there is a compound Na₂O.2SiO₂.9H₂O bounded by the curve LMN and the tie-lines converging on E.

A compound corresponding to this formula has not yet been obtained from solutions at ordinary temperatures, though Morey has attained the separation of crystalline Na₂O.2SiO₂ from solution at 400°C and from melts at about 1000°C. Also, much evidence from conductivity, transport numbers, hydroxyl and sodium ion concentration measurements, already described, may be adduced to show the existence of a compound of the formula Na₂O.2SiO₂ in solution at ordinary temperatures.

A number of investigators have obtained products containing 2 to 4 or more molecules of SiO₂ to one molecule of alkali oxide, but the preparative methods used are, in every case open to question, and the products were always amorphous. Most of these methods fall into two classes:—

- (1) precipitation with alcohol
- (2) determination of the ratio, alkali oxide to silica, in the saturated solution.

By the first method Forchhammer⁶ obtained Na₂O.3SiO₂, but Ordway⁷ has shown that this method leads to wholly erroneous results, because the composition of the precipitate depends on the concentration of the solution, the proportion of alkali present, and the amount of alcohol added, and varies continually with variation of any of the above factors. The second way is obviously wrong.

More recently Schwarz and Menner⁸ claim to have obtained definite crystalline compounds of compositions corresponding to Na₂O.SiO₂; Na₂O.-2SiO₂; Na₂O.3SiO₂ by fusing pure quartz with Na₂CO₃ at 1150 C. They obtained Na₂O.2SiO₂ and Na₂O.3SiO₂ as glasses which they state, transformed into definite compounds by heating at 700°C, for from 50-100 hours. Morey,

by his hydrothermal quenching method, obtained $\text{Na}_2\text{O} \cdot 2\text{SiO}_2$ but not $\text{Na}_2\text{O} \cdot 3\text{SiO}_2$.

Schwarz and Menner do not state that they examined these crystalline silicates microscopically, nor do they give any measurements of angles as Morey does.

It was found impossible to investigate the system beyond the point N, not only because of the extreme viscosity of the solutions, but also of the more serious obstacle due to mass setting to what was presumably a gel.

The fact that some or most of the silica in this region exists as colloidal silica renders the application of the phase rule invalid. If a sodium silicate dissolves in water with the formation of colloidal silica, the process will certainly go on until some more or less definite end point is reached; but this presumed equilibrium is in no way determined by the real solubility of sodium silicate itself. This objection cannot be raised against that part of the system represented by the region lying between $\text{Na}_2\text{O} \cdot \text{SiO}_2$ and the $\text{H}_2\text{O} : \text{Na}_2\text{O}$ side of the component triangle, as all the previous work described herein points to the fact that the metasilicate, is certainly not colloidal in solution. It also seems probable from the previous work by the author that there is no colloidal matter, or at most, very little, in solution in the region up to 1:2. The fact that the tie-line from E to the H_2O apex cuts the saturation curve of $\text{Na}_2\text{O} \cdot 2\text{SiO}_2 \cdot 9\text{H}_2\text{O}$ shows that this compound has a true solubility in water at this temperature. In spite of the colloidal nature of the region beyond N to the $\text{H}_2\text{O} : \text{SiO}_2$ side of the component triangle, we are quite justified in concluding that a compound $\text{Na}_2\text{O} \cdot 2\text{SiO}_2$ does exist in solution.

Summary

- (1) Previous work in this field has been surveyed and summarised.
- (2) An investigation of the ternary system $\text{Na}_2\text{O} : \text{SiO}_2 : \text{H}_2\text{O}$ at 25°C has been carried out and the results shown graphically.
- (3) Towards the $\text{H}_2\text{O} : \text{SiO}_2$ side of the system the solutions became colloidal and so invalidated further work.
- (4) Two compounds only are indicated as stable in solution,— $\text{Na}_2\text{O} \cdot \text{SiO}_2$ and $\text{Na}_2\text{O} \cdot 2\text{SiO}_2$.
- (5) Na_2SiO_3 crystallises with 9, 6 and 2.5 H_2O ; $\text{Na}_2\text{O} \cdot 2\text{SiO}_2$ with 9 H_2O .

I wish to thank the Commissioners of the 185 Exhibition Scholarship which has enabled me to carry out this investigation, and to express my gratitude to Professor Donnan, at whose suggestion this work was undertaken, for his constant kindly interest and advice.

THE APPLICATION OF THE ELECTRON TUBE TO POTENTIOMETRIC TITRATIONS*

BY JOHN WARREN WILLIAMS AND THEODORE A. WHITENACK

The introduction of the electron or vacuum tube has made possible many accurate measurements in the field of chemistry as well as in physics. It is, of course, the familiar instrument used as both detector and amplifier in modern radio-communication, and need not be described here.

Thus far, there has been no extensive application of the electron tube to potentiometric titrations.¹ There is, however, every reason to believe that the application should be extensive, since the tube may be caused to function essentially as a potentiometer which draws virtually no current from the titration cell, neither can any current be supplied to the cell through the tube under proper working conditions.

Goode² was the first to apply the electron tube to a potentiometric titration. He showed "that the three-electrode vacuum valve ("audion") presents almost the ideal case of a "voltmeter" which draws no current from the source to be measured, and can therefore be employed as a continuous-reading instrument for determining the concentration of the hydrogen ion". In the second paper this investigator has described "an improved, continuous-reading hydrogen-ion meter" which makes "use of the three-electrode vacuum tube as a voltmeter, and as a direct current amplifier". The statement is made that the device serves to indicate the potential between any two electrodes ordinarily used in electro-chemical work; but the article, as its title indicates, intends the description of an apparatus for the determination of hydrogen ions.

Calhane and Cushing³ applied an arrangement similar to that of Goode to the accurate titration of dilute sodium chloride solutions with silver nitrate. Treadwell⁴, making use of a similar apparatus, has studied this same precipitation reaction. His arrangement differs from that of the previous investigators in that a potential (1.6 volts) has been introduced into the circuit in series between the negative or indicator electrode of the titration cell, and the grid of the electron tube.

The purpose of this paper is to show that the electron tube may be applied not only to the determination of hydrogen ion concentration and of the end point of certain precipitation reactions but to potentiometric titrations in general, at least to those which may be followed with analytical accuracy by the potentiometric method. This has been accomplished by a study of certain chemical reactions of the various types which have already been submitted to detailed investigation by the potentiometric method.

⁴ Treadwell: Helv. Chim. Acta, **8**, 89 (1925).

Method

The method used is similar in principle to that of Goode, Calhane and Cushing, and Treadwell. The electrode whose potential indicates the change in concentration of the ion to be titrated is called the indicator electrode. Its potential may be determined by means of another electrode which has a constant potential, the two electrodes giving an electromotive force which can be measured. The change in this electromotive force during a potentiometric titration is then equal to the change of potential of the indicator electrode. At the equivalence point of the titration the rate of change of this

FIG. 1

potential with a small change in concentration assumes a maximum value. If now, the potential of the indicator electrode be impressed upon the grid element of an electron tube the value of the plate current will be regulated by the change of potential of the electrode. The plate current may be measured by an ordinary wall galvanometer with a suitable shunt. The equivalence point is indicated by the position of the break in the curve obtained by plotting cubic centimeters of titrating solution added as abscissae against galvanometer deflections as ordinates.

Apparatus

A diagram of the apparatus used is shown in Fig. 1. The vacuum tube was a Cunningham amplifier and detector, CX-299, whose filament operates normally at 3 volts, drawing 0.06 ampere. In the experiments to be described it was found most satisfactory to operate the tube at 0.04 ampere. The source of current, the "A" battery in the diagram, was an ordinary lead storage cell connected to the filament through a rheostat, R, and an ammeter, Am, by means of which the filament current was kept constant. The plate, or "B" battery consisted of several 22.5 volt units, any number of which could be used for best operation of the tube. The characteristics of the tube and galvanometer were such that normally 22.5 volts were used. The indicator electrode of the titration cell, T.C., was connected directly to the grid element of the tube and the calomel or reference electrode was connected through a battery, "C", of one or two dry cells, to the negative of the filament.

Experimental Procedure

The procedure may be illustrated by the description of a typical experiment in which a definite volume of a $n/10$ solution of ferrous ammonium sulfate was oxidized by a $n/10$ solution of potassium dichromate in acid solution. The apparatus was connected as above, the indicator electrode being simply a bright platinum wire. When the filament current was constant at 0.04 ampere a galvanometer shunt was adjusted so that a deflection of exactly 25

FIG. 2

Oxidation-Reduction Reactions

1. $\text{HCrO}_4' + 7\text{H}^+ + 3\text{Fe}^{++} \rightarrow \text{Cr}^{+++} + 4\text{H}_2\text{O} + 3\text{Fe}^{+++}$
2. $2\text{MnO}_4' + 2\text{H}_2\text{O} + 3\text{Mn}^{++} \rightarrow 5\text{MnO}_2 + 4\text{H}^+$
3. $\text{I}_2 + 2\text{S}_2\text{O}_3' \rightarrow \text{S}_4\text{O}_6' + 2\text{I}'$

centimeters on the scale was obtained. The potassium dichromate was titrated into the ferrous ammonium sulfate solution. At first, several cubic centimeters were added at a time, but, as the equivalence point was approached, readings of the galvanometer were taken more and more frequently. As the titration continued the potential of the indicator electrode became slightly more negative until the equivalence point was reached and the "break" came. This increasingly negative potential caused the plate current, and therefore the galvanometer deflection, to be decreased. The result of the titration was obtained from a curve, where the abscissae represent cubic

centimeters of titrating solution and the ordinates represent the corresponding galvanometer deflections. It is usually assumed that the inflection point indicates the equivalence point precisely, although in certain systems, especially in the case of oxidation-reduction reactions, the equivalence point is known to be somewhat beyond this point.¹

FIG. 3

Miscellaneous Reactions

4. Precipitation: $3\text{Zn}^{++} + 2\text{K}_4\text{Fe}(\text{CN})_6 \rightarrow \text{Zn}_3\text{K}_2[\text{Fe}(\text{CN})_6]_2$
5. Neutralization: $\text{H}^+ + \text{OH}^- \rightarrow \text{H}_2\text{O}(\text{HAc} + \text{KOH})$

Experimental Results

Typical experimental results are shown in the accompanying graphs (Figs. 2 and 3) where galvanometer deflections are plotted against cubic centimeters of titrating solution added. The systems studied were chosen at random from the classification of reactions which give accurate end-points by the potentiometric method given in chapter "Electrometric Methods in Chemistry" of Taylor's "Treatise on Physical Chemistry".² On the basis of this classification three oxidation-reduction reactions³ (shown in Fig. 2) and

¹ Kolthoff and Furman: "Potentiometric Titrations", Chaps. V and VI (1926).

² Taylor: "Treatise on Physical Chemistry", pp. 851-854 (1924).

³ We are indebted to Mr. Penrose S. Albright for the experimental work on the sodium thiosulphate-iodine system.

one precipitation reaction and one neutralization reaction (shown in Fig. 3) were studied. Each curve gives the result of a single representative titration. The reactions studied were as follows:

Oxidation-Reduction Reactions:

1. $\text{HCrO}'_4 + 7\text{H}' + 3\text{Fe}'' \longrightarrow \text{Cr}''' + 4\text{H}_2\text{O} + 3\text{Fe}'''$
2. $2\text{MnO}'_4 + 2\text{H}_2\text{O} + 3\text{Mn}'' \longrightarrow 5\text{MnO}_2 + 4\text{H}'$
3. $\text{I}_2 + 2\text{S}_2\text{O}_3'' \longrightarrow \text{S}_4\text{O}_6'' + 2\text{I}'$

Precipitation Reaction:

4. $3\text{Zn}'' + 2\text{K}_4\text{Fe}(\text{CN})_6 \longrightarrow \text{Zn}_3\text{K}_2[\text{Fe}(\text{CN})_6]_2$

Neutralization Reaction:

5. $\text{H}' + \text{OH}' \longrightarrow \text{H}_2\text{O} (\text{HC}_2\text{H}_3\text{O}_2 + \text{KOH})$

The accuracy and consistency of the measurements are illustrated by the fact that six consecutive observations made on the system, ferrous ammonium sulfate-potassium dichromate, gave an end-point (taken arbitrarily as the point of inflection of the curve) at 20.30 cc. of the latter solution, with a maximum deviation of 0.05 cc. The end-point determined by the usual potentiometric method also gave 20.30 cc with deviations of the same order. Excellent agreement was found in all cases between the end-points determined by the two potentiometric methods and those determined by the usual volumetric methods, except in the case of the determination of zinc with potassium ferrocyanide where the potential break occurred before (0.2 cc) the volumetric end-point. The results of this titration are in excellent agreement with those of Kolthoff¹ who, using the ordinary potentiometric method, found that the potential break occurred before the equivalence-point was reached.

Conclusion

The simple apparatus which has been described above makes general the application of the electron tube to potentiometric titrations, at least to those reactions which give analytical accuracy when titrated potentiometrically. It has all the advantages of electro-titration, in addition it gives a continuous automatic record of the progress of a reaction, since the electron tube may be regarded as a direct-reading, sensitive voltmeter which draws no current from the titration cell. The apparatus required is inexpensive and readily obtainable, being assembled entirely from standard instruments which are now manufactured in large quantities and at low cost.

Summary

1. An apparatus which makes general the application of the electron tube to potentiometric titrations has been described.
2. Using this apparatus three oxidation-reduction reactions, one precipitation reaction and one neutralization reaction were studied. These

¹ Kolthoff and Furman: "Potentiometric Titrations", p. 268 (1926).

systems were typical of those which give analytical accuracy when titrated potentiometrically.

3. The apparatus described has all the advantages of electro-titration, in addition it has several others which make it suitable for technical and instructional purposes.

ADSORPTION BY METALLIC HYDROXIDES. II. ADSORPTION OF ACIDS, ALKALI AND SALTS BY PRECIPITATED FERRIC HYDROXIDE

BY KSHITISH CHANDRA SEN

Though a certain amount of experimental work exists in the literature on the adsorption of acids and acid ions by colloidal ferric hydroxide in course of its precipitation, no comparative study of the adsorption of acids by precipitated ferric hydroxide seems to have been made. Freundlich¹ cites the experiments of Wöhler, Pluddeman and Wöhler² to the effect that ferric oxide adsorbs benzoic acid about ten times as strongly as acetic acid, but besides one or two such references, no systematic attempt has been made. Even the direct estimation of adsorption of ions by colloidal ferric hydroxide has been made by only a few investigators, the reason being that hitherto the order of adsorption of ions has been assumed to be the same as that obtained from the order of the precipitating power of the ions on the colloidal solutions. The usual difficulty of working with precipitated substances however is that the amount of adsorption is generally small and hence the measurements are liable to be in error. As with hydrated ferric, aluminium, and chromium oxides, no such difficulty has been experienced, the adsorption values being quite large, this procedure has been adopted. Two advantages are thereby gained over the colloidal solutions; (1) the amount of the adsorbent may be varied at will in the same volume of the solution and (2) the objection that during coagulation the colloid may adsorb some water does not come in. Further the precipitated substances can be obtained chemically almost pure, and hence the adsorption values will not be vitiated by the presence of other ionic impurities. Owing to these reasons, it was thought advisable to use a freshly precipitated and well washed hydrated ferric oxide as the adsorbent.

The method of experiment was the same as described in the case of arsenious acid. The sample of the ferric hydroxide was prepared about twenty-five days before the experiment, and on experimenting showed no ageing effect. The excess of acid in the supernatant liquid was estimated volumetrically by means of carbonate-free alkali using phenolphthalein as the indicator and test experiments showed that the method was quite accurate. To get comparative results, equivalent concentrations of acids were used in almost all cases; only in the cases of formic and acetic acid, a slightly higher concentration was used. The acids were used in rather dilute solutions, so that a high value of adsorption may be obtained and in certain cases dilute solution was necessary to include some of the less soluble acids. The results obtained are shown in Table I.

TABLE I

Adsorption of acids by hydrated ferric oxide

Amount of oxide = 0.4882 gr.

Vol. = 100 cc; KCl = 0.05 mole per litre

Time = 20 hours

Original strength of the acids = 0.4615 milli-equivalents per 100 cc.
 The strength of formic and acetic acids was 0.4627 milli-equivalents per 100 cc.

No.	Acid	Amount of adsorption milli-equivalents	Dissociation constant $\times 10^2$
1.	Formic	0.4147	0.021
2.	Acetic	0.3978	0.0018
3.	Monochlor-acetic	0.4326	0.155
4.	Trichlor-acetic	0.4350	—
5.	Propionic	0.3846	0.0013
6.	Butyric	0.3846	0.0015
7.	Valeric	0.3870	0.0016
8.	Caproic	0.3842	0.0014
9.	Benzoic	0.4373	0.0060
10.	m-Oxy-benzoic	0.4349	0.0087
11.	o-Amido-benzoic	0.4325	0.00104
12.	m-Amido-benzoic	0.4253	0.0016
13.	p-Amido-benzoic	0.4300	0.0012
14.	Hippuric	0.4422	0.022
15.	Succinic	0.4422	0.0068
16.	Dibrom-succinic	0.4277	5.0
17.	m-Toluic	0.4349	0.0051
18.	o-Toluic	0.4300	0.012
19.	Malic	0.4470	1.20
20.	Oxalic	0.4470	10.0
21.	Racemic	0.4422	0.097
22.	Meso-tartaric (inactive)	0.4470	—
23.	l-Tartaric	0.4422	0.097
24.	Lactic	0.4277	0.014
25.	Malonic	0.4373	0.158
26.	Citric	0.4470	0.082
27.	Hydrochloric	0.4422 (?)	—
28.	Sulphuric	0.4422	—

Relatively strong acids like hydrobromic, nitric, etc, could not be examined and the result with hydrochloric acid is also somewhat doubtful owing to the ease with which these acids peptise ferric hydroxide. The supernatant liquid was turbid even in presence of .05 mole KCl. It will be evident from these results that at the dilution studied, the amount of adsorption is quite high and the percentage of adsorption lies between 80 to 95 per cent. Obviously in such high adsorptions, the effect of concentration of the original solution

is masked in some cases and, owing to this reason, some of the adsorption values have been found to be equal. A second series of determination was therefore made with varying concentrations of the acids using the same adsorbent, Tables II-XIII.

Adsorption of salts and alkali.

In the foregoing pages, the adsorption of acids by hydrated ferric oxide has mainly been given. It has however been shown in the previous paper that both sodium arsenite and caustic soda are adsorbed by ferric hydroxide, and in the case of sodium arsenite mainly the arsenite ion was adsorbed. In this connection the adsorption of many other salts such as potassium sulphate, sodium citrate, sodium phosphate, potassium permanganate, potassium dichromate, etc, by precipitated hydroxide was determined, but, owing to the very small amounts of adsorption, quantitative results could not be obtained. It was however found that with salts like citrate, phosphate, etc, appreciable adsorption of the negative ions takes place on shaking a solution of these salts with ferric hydroxide, a corresponding amount of alkali being set free, which can be tested by means of phenolphthalein. The adsorption therefore seems to be preferential. As it is known that alkali is also adsorbed by ferric hydroxide, a comparative study of the adsorption of acid and alkali seemed desirable. Hence some adsorption experiments have also been made with the ferric hydroxide No. 3 and caustic soda of almost the same concentration as has been used in the case of sulphuric acid. The results are given in Table XIV.

TABLE XIV

Amount of $\text{Fe}_2\text{O}_3 = 0.2559$ gr.

Original conc. of NaOH milli-equivalents per 100 cc	Conc. of the soln. after adsorption	Adsorption per gm. adsorbent
0.9434	0.7401	0.7949
0.7548	0.5801	0.6828
0.5659	0.4098	0.6098
0.3773	0.2399	0.5368
0.2830	0.1500	0.5199

It may be assumed that at the dilution studied, both the sulphuric acid and caustic soda are practically completely ionised. Hence if these results are compared to that given in Table VII, it will be noticed that H^+ ion is much more adsorbed by ferric hydroxide than OH^- ions. There is no doubt that this is connected with the chemical nature of the adsorbent, which is a basic substance. A similar instance is known in the case of manganese dioxide.¹ This substance is acidic in nature and it adsorbs both the acidic and basic portions of several substances such as copper sulphate. The adsorption of the basic portion is however much greater than that of the acidic one, and when the adsorption of acids and bases are studied, it is seen that H^+ ion is much less adsorbed than OH^- ions.

THE ADSORPTIVE FORCE OF SILICA FOR WATER

BY P. G. NUTTING*

One of the serious obstacles to the progress of colloid chemistry is the lack of knowledge of the forces involved in adsorption and of the variation of these forces within their minute range of operation. The method here described gives reasonable results checking well with known facts in the case of silica and water. It is rather roundabout; but no more direct method is apparent at present. Heat of wetting is found as a function of thickness; then forces are calculated from its differential.

Parks¹ found the heat of wetting of dry silica by water to be 0.0105 cal/cm², independent of the size of the surface and the same for precipitated silica, sand and glass wool. Bellatti and Finazzi² determined the heat of wetting of silica having varying moisture content. Their data³ are reproduced in Table I.

TABLE I
Heat of Wetting of Silica of Varying Moisture Content

A Adsorbed H ₂ O/gm SiO ₂	B Cal/gm of SiO ₂	C Cal/gm 26.0-B	D Depth of H ₂ O × 10 ⁶	E Cal per cm ² × 10 ⁴

0.0238	18.29	7.71	0.95	3.08
.0535	12.33	13.67	2.14	5.47
.0859	9.17	16.83	3.44	6.73
.1292	7.61	18.39	5.17	7.36
.1883	6.50	19.50	7.53	7.80
0.2736	5.25	20.75	10.94	8.30
.3995	3.70	22.30	15.98	8.92
.4635	2.94	23.06	18.54	9.22
.5648	1.66	24.34	22.59	9.74
.6478	0.90	25.10	25.91	10.04
.7694	0.19	25.81	30.78	10.32

Columns A and B are the original data of Bellatti and Finazzi except for the initial value 26.0 obtained by extrapolation. The specific surface of the silica used is $26 \div 0.0105 = 25000$ cm²/gm. The water of column A, spread over this surface gives the thickness of adsorbed layer given in D. The heat liberated (in cal/cm²) by adsorption is given in E.

Parks, in a later paper⁴ gives these data and divides E by D thus obtaining cal/cm²/cm, which is the mean energy density from the silica surface out to

the depth shown in D. However the data of real significance is rather to be obtained by plotting E as a function of D and then differentiating this function graphically. This derivative is the rate of decrease of specific energy content with increase of water film thickness outward from the silica surface. The data obtained by this procedure are given in Table II and illustrated by the curves of Fig. 1. Thickness of water film is represented by z in $\text{cm} \times 10^6$ and energy by c in $\text{cal/cm}^2 \times 10^4$. dc/dz is in $\text{cal/cm}^2/\text{cm}$.

FIG. 1

TABLE II

z	c	dc/dz	$P(\text{Atm.})$	z	c	dc/dz	$P(\text{Atm.})$
0.0	0.0	420	17410	5.0	7.32	22.0	912
0.5	1.8	353	14630	7.5	7.72	16.5	684
1.0	3.1	274	11360	10.0	8.18	15.1	626
1.5	4.4	205	8500	15.0	8.82	12.1	502
2.0	5.3	157	6510	20.0	9.42	11.5	477
2.5	6.0	120	4970	25.0	9.94	8.7	361
3.0	6.45	88	3650	30.0	10.28	5.6	232
4.0	7.04	44.5	1845				

The differential curve turns sharply at thicknesses between 4 and 5×10^{-6} cm representing a layer of water between 100 and 120 molecular diameters deep. It is straight and steep near the origin indicating a high but uniformly decreasing rate of falling off in the energy of adsorption. That energy is by no means confined to the first molecular layer nor is there any apparent break after the first. Dissociation of water into H and OH is indicated but not

proven by this curve without additional data on the rate of decrease in density. Since the depths of water were determined by weighing, increased densities due to close packing of staggered H and OH ions or by actual compression would have the effect of slightly compressing the abscissae near the origin and therefore of enhancing the slope of the energy curve. On the other hand, dissociation would use up energy (at the expense of adsorptive forces) and therefore flatten both curves. Further out, beyond a layer about 175 molecules deep, the differential curve becomes very low and again of uniform slope.

Interest centers on the two straight portions of the differential curve. Near the silica surface ($z = 0$) the slope is uniformly 143×10^6 cal/cm²/cm², and for that straight portion (in cal/cm²/cm)

$$dc/dz = 420 - 143 z$$

Reducing calories to ergs by means of the factor 42×10^6 ergs/calorie (J) and remembering that $Jdc = Pdz$ where P is the pressure in dynes/cm² we get

$$\begin{aligned} P &= (17640 - 6006 z) \times 10^6 \text{ dynes/cm}^2 \\ &= 17410 - 5928 z \text{ in atmospheres.} \end{aligned}$$

In these equations z is still in the units of the table and figure, namely 10^{-6} cm.

The maximum pressure (at the surface, $z = 0$) of 17410 atmospheres, is moderate compared with some estimates running as high as 37000 atm. arrived at by differential density determinations, known compressibility and estimates of thickness. This simple law of force (P above) is reasonable and holds very well for a thickness of at least 50 molecular diameters, fairly well to 100 where evidently conditions are modified. If conditions existing near the surface held indefinitely, the pressure would fall to zero ($P = 0$) at $z = 2.94 \times 10^{-6}$ cm or 73 molecular diameters. The pressure gradient near the surface, namely $5928 \text{ atm}/10^{-6} \text{ cm} = 237 \text{ atmospheres per molecular layer of water } 4 \times 10^{-8} \text{ cm deep}$. Allowing for the known compressibility of water in compressing the z scale near the origin (region of high pressures) this maximum pressure gradient (237 atm./molec. diam.) would be reduced and the pressure gradient curve straightened still further, out to about $z = 4 \times 10^{-6}$ cm. There is no apparent justification for attempting to fit an inverse power law to the falling off of force with distance. It can be done with a double exponential but the fit is not as good and the formula has no rational physical basis.

The slope of the differential (dc/dz) curve falls to 0.450 cal/cm²/cm² at a distance from the silica surface (lower straight portion). For this portion of the curve

$$dc/dz = 19.6 - 0.450 z \text{ (cal/cm}^2\text{/cm)}$$

and reducing to pressure as before

$$\begin{aligned} P &= (824 - 18.9 z) \times 10^6 \text{ (dynes/cm}^2\text{)} \\ &= 813 - 18.6 z \text{ (atmospheres)} \end{aligned}$$

from which $P = 1$ for $z = 43.7 \times 10^6 \text{ cm} = 0.41 \mu = 1090$ molecular diameters of water ($4 \times 10^{-8} \text{ cm} = 4 \text{ A.U.}$) If this same pressure gradient existed back to the surface $z = 0$, the pressure then would be $P = 813 \text{ atm.}$ Within this region of uniform pressure gradient, the pressure falls off at the rate of $0.74 \text{ atm. per molecular layer of water.}$

The pressures and pressure gradients deduced above for the adsorption of water on silica are reasonable from many angles and point the way to further deductions in the realm of hydration and solution. It is not to be overlooked that if the solid pulls on the adsorbed liquid, the liquid must pull on the solid. The pull deduced above (17000 atm.) for the maximum exerted by silica on water is of the same order as the tensile strength of quartz. Hence if the water molecules (or H and OH ions) can but secure a proper toe hold or arch themselves, they would be expected to pull the silica out into solution, or into hydration at least. Even quartz does in fact slowly hydrate and go into solution and suspension. I have obtained over half a gram per liter in permanent suspension from powdered silica heated for six hours in distilled water in a platinum dish.

Liquid solvents for solids must therefore be adsorbed by the solid with a maximum force exceeding its tensile strength and solution will continue until equilibrium is restored by the added pressure of material in solution. The adsorption of water on silica involves considerable release of energy partly because of the low stability of silica in water. If soda (or potash) be added to the water, the sodium ions are still more strongly adsorbed than the water but they pull the silica into solution, thus using up (in dissociating and expanding the silica) the energy released by adsorption.

THE VELOCITY OF REACTION AND ENERGY OF ACTIVATION OF HALOGEN COMPOUNDS

BY DAVID HENRY PEACOCK

In a very large number of cases certain regularities have been observed in the effect of substituents upon the reaction velocity of halogen compounds with other reactants such as water, amines, sodium allyl oxides, and potassium iodide. The alternating character of these effects has been extensively studied in connection with the theories of Flurschein and of Lapworth and Robinson. It has been shown by the present author¹ that this alternating character is also observed in the energy of activation of *m*- and *p*-nitrobenzyl chlorides with aniline, *p*-toluidine, *o*-toluidine and dimethylaniline. A tertiary base was used because with a primary or secondary base there is always the possibility of two reactions (1) the formation of a salt of pentavalent nitrogen (2) direct removal of hydrogen from combination with the nitrogen. The latter possibility may be considered as somewhat remote in the reactions under consideration.

It has now been found that methyl-ethyl-aniline with *m*- and *p*-nitrobenzyl chloride and dimethyl-*m*- and *p*-toluidine with benzyl chloride also show this alternating effect. The measurements were carried out in a manner similar to those already described (*loc. cit.*) and are given in Table I.

TABLE I
Energies of Activation:—Tertiary Bases

Methyl alcohol solution at 35°C and 45°C.

[Base] = 0.4M, [Halogen compound] = 0.1M

	k_{35}	E
Ethyl methyl aniline and meta-nitrobenzyl chloride.	5.01×10^{-4}	8335
" " " " para- " "	3.01×10^{-4}	8964
Dimethyl-para-toluidine and benzyl chloride	6.58×10^{-3}	13470
" meta- " " " "	4.74×10^{-3}	14850

The second case is interesting as showing the alternating effect of a methyl group upon the energy of activation of the nitrogen atom in the reaction concerned. Similar cases are being studied. The work of Holleman² on the rates of hydrolysis of substituted benzyl chlorides provides data from which a series of energies of activation can be calculated, Table II.

It is apparent that with exception of the first pair of reactions that reaction which is faster has the smaller energy of activation. Holleman (*loc. cit.*) drew attention to this in another way by stating that the differences between the reaction velocities tended to become smaller as the temperature increased.

¹ Peacock: J. Chem. Soc., 127, 2177 (1925).

² Rec. Trav. chim., 41, 646 (1927).

TABLE II
Energies of Activation: Hydrolysis Reaction
(Holleman: loc. cit)

Halogen compound	k (30°)	k ₁ /k ₁₁₅ °	E/10 ⁴
<i>p</i> -CH ₃ .C ₆ H ₄ .CH ₂ Cl	1.04	157	2.04 cals.
<i>m</i> - " "	0.144	150	2.01
<i>p</i> -Cl.C ₆ H ₄ .CH ₂ Cl	0.052	184	2.10
<i>m</i> - " "	0.0152	242	2.21
<i>p</i> -BrC ₆ H ₄ CH ₂ Cl	0.0457	170	2.07
<i>m</i> - " "	0.0147	227	2.18
<i>p</i> -NO ₂ .C ₆ H ₄ CH ₂ Cl	0.00491	234	2.19
<i>m</i> - " "	0.0063	222	2.17

From the results given by Holleman¹ it is possible to calculate the energies of activation for the reaction between nitro 2:4 dichlorobenzene or nitro 2:5 dichlorobenzene and sodium methoxide in one case and diethylamine in the other. The results are collected below:—

(1) Sodium Methoxide.

Nitro 2:4 dichlorobenzene	Nitro 2:5 dichlorobenzene
k ₂₅ = 0.030	0.0063
k ₅₀ /k ₂₅ = 2.09	1.92
E (50/25) = 2.31 × 10 ⁴	2.24 × 10 ⁴
R ₈₅ /R ₅₀ = 3.09	3.24
E (85/50) = 2.24 × 10 ⁴	2.27 × 10 ⁴

(2) Diethylamine

k ₈₅ °	0.027	0.0067
R ₁₁₀ /R ₈₅	3.15	3.43
E (110/85)	1.36 × 10 ⁴	1.34 × 10 ⁴

The faster reaction has the smaller energy of activation in only one pair of these results namely in the reaction between sodium methoxide and nitro 2:5 dichloro benzene at 50°C and 85°C. It must be remarked however that in nitro 2:4 dichloro benzene both chlorine atoms are labile (cf Holleman: loc. cit. for velocity coefficient with *o*- and *p*-nitrochloro benzene) and this is bound to complicate the results.

If the hypothesis of Robinson and Lapworth with regard to the alternating effect of substituents upon the reactivity of a labile atom be interpreted in the sense that of two compounds that is more reactive which is activated more easily and if this interpretation be applied to the cases tabulated above it will be seen that where the hypothesis demands that one substance should be more reactive than another then the energy of activation of the more reactive substance is less than that of the less reactive, e.g.:

¹ Rec. Trav. chim., 35, 1 (1915).

Methyl benzyl chloride ($\text{CH}_3\cdot\text{C}_6\text{H}_4\cdot\text{CH}_2\text{Cl}$) does not behave in accordance with the hypothesis and the results given by nitro 2:4 dichloro and 2:5 dichloro benzene are contradictory. Bearing in mind the difficulty of obtaining accurate results for the energy of activation the agreement between the order of these values and those predicted by the Robinson and Lapworth hypothesis seems too close to be fortuitous and supports the assumption that the energy of activation of a substance shows alternating effects which can be predicted with the help of the Lapworth-Robinson hypothesis. It is of course understood that the term energy of activation of a substance means energy of activation with a particular reactant.

E (aniline) = 18030 cal.

E (Benzyl chloride) = 13410 cal.

E (water) = 2.10×10^4 cal.

E (aniline) = 17280 cal.

E (Benzyl chloride) = 14850

E (water) = 2.21×10^4 cal.

In passing it may be remarked that the relative reactivities of the *m*- and *p*-dimethyl toluidines while in accordance with the Lapworth and Robinson hypothesis do not agree with the Flurschein hypothesis as ordinarily applied. Toluene shows reactivity in the *o* and *p* positions and therefore according to the Flurschein hypothesis the nitrogen atom in the *m* position should possess excess of residual affinity and be more reactive than the nitrogen atom in the *p* position, the opposite is actually the case. Further work is proceeding on this subject.

The temperature coefficients of two simultaneous reactions will naturally affect the relative amounts of the products formed. If the faster reaction has the greater temperature coefficient then the proportion of product formed in the greater amount will increase as the temperature rises. If, on the other hand, the product formed in the greater amount is produced by a reaction with a lower temperature coefficient i. e. a smaller energy of activation, then the relative amounts of the two products will approach one another as the temperature rises and may even change in ratio. Conclusions as to reactivity based on the relative quantities of two products formed at a particular temperature would thus appear to attach undue importance to relative velocities at an arbitrary temperature.

In the cases considered the alterations in velocity were produced by the alternating effect of a particular substituent and the difference in velocities is much more marked than the difference in energies of activation. If instead of examining the effect upon velocity of the change in position of a particular substituent we study the effect of substituting one halogen for another then the difference in velocities is often of a much higher order than the difference of temperature coefficients and therefore of energies of activation. Perhaps the earliest case studied is the reaction velocities of allyl halogen compounds with sodium and potassium ethoxide examined by Conrad and Bruckner¹ who found that the relative rates of reaction for chlorides, bromides and iodides were approximately as 1:70:140 while the temperature coefficients of all three reactions were approximately the same. Menshutkin² found that the relative rates of reaction for alkyl chlorides, bromides and iodides with amines were approximately as 1:100:700. The temperature coefficients and energy of activation for one particular amine with the halogen derivative of a particular allyl compound in the same solvent do not seem yet to have measured but from the results of Jones and Preston³ the energy of activation for the reaction between allyl iodide and dimethylaniline is found to be 9362 and for tri isoamyl amine 9702 in absolute alcohol. The velocity constant for the first reaction at 25°C was 0.656. E. R. Thomas⁴ for the velocity constant of the reaction allyl bromide and dimethyl aniline found the value 1.08 at 40°C in absolute alcohol. The iodide would thus react probably twice as fast at the same temperature. Measurements have been made of the velocity constants of the reaction between diethyl aniline and benzyl chloride and benzyl bromide in methyl alcohol; the constants at 35°C are .000178 and .00473. The energies of activation for the same reactions⁵ are 14550 and 15560. These results are tentative. Slator and Twiss⁶ examined the rates of reaction of a number of halogen compounds with sodium thiosulphate. Some of their results are given in Table III.

⁴ J. Chem. Soc., 103, 592 (1913).

⁵ $C_6H_5N(C_2H_5)_2$ = 0.8 M in benzyl chloride reaction and 0.4 M in benzyl bromide reaction.

⁶ J. Chem. Soc., 95, 99 (1909).

TABLE III

Rates of Reaction and Temperature Coefficients for Alkyl Halides and Sodium Thiosulphate

CH ₃ I	$k_{15}^{\circ} = 0.280$	$(k_t + 10^{\circ})/k_t = 3.05$	Iodides
CH ₃ ICOOC ₂ H ₅	$k_{15}^{\circ} = 2.55$	" = 2.75	
CH ₃ Br	$k_{15}^{\circ} = 0.29$	" = 3.1	Bromides
CH ₃ BrCOOC ₂ H ₅	$k_{15}^{\circ} = 2.36$	" = 2.75	
CH ₃ Cl	$k_{15}^{\circ} = 0.0066$	" = 3.2	Chlorides
CH ₃ Cl.COOC ₂ H ₅	$k_{25}^{\circ} = 0.060$	" = 2.9	

The final impression produced by all these results is that while the substitution of one halogen for another may make a large effect on the velocity constant the effect on the energy of activation is very small. If the energy of activation is related to the stability of the halogen linkage in the allyl compounds then it is probably also related to the energy required to displace the electrons constituting that bond and to the energy required to break the bond. No data seem available bearing directly on this point but it is significant that the heats of combustion of halogen compounds show no large differences and are usually of the order $\text{RCl} > \text{RBr} > \text{RI}$. Indirect evidence as to the stability of the HX electronic bond is perhaps afforded by the following figures as to their ionisation potentials given by Mackay¹ $\text{HCl} = 13.7$ $\text{HBr} = 13.3$ $\text{HI} = 12.7$ volts. The hydrogen compounds are not the most suitable to choose in view of the peculiarities of hydrogen but no other data seems available.

Two other points are of interest in this connection. Menshutkin² found that in benzene solution the reaction velocity of *m* toluidine with allyl bromide was greater than that of *p*-toluidine and so also with methyl bromide. In acetone solution however both bromides reacted faster with *p*-toluidine. In the case of allyl bromide it was found that also in brom naphthalin *m*-toluidine reacted faster than *p* whereas in acetophenone and propyl alcohol the *p*-compound reacted faster. The effect of a methyl group in the *m* or *p* position thus depended on the solvent. With 2:4 dimethyl aniline and 2:5 dimethyl aniline the compound with the methyl group in the *p* position reacted faster than the *m* in both benzol and acetone. Thus the anomalous effect of a methyl group in the *m* or *p* positions is shown only by *m*- and *p*-toluidine in certain solvents.

Rheinlander³ found that the substitution of iodine for chlorine in 2:4 dinitro chloro benzene produced anomalous results in that the reaction velocity of dinitro-iodo-benzene with certain bases was lower than that of dinitro-chlorobenzene. The effect then of a change in the position of a substituent upon reaction velocity may depend upon the solvent used and the effect of substituting iodine for chlorine depends on the reaction studied.

¹ Phys. Rev., (2) 24, 324 (1924).

² Z. physik. Chem., 34, 157 (1900).

³ J. Chem. Soc., 123, 3099 (1923).

Such considerations raise the question as to the suitability of velocities of reactions as a measure of reactivity. One obvious disadvantage which has been referred to by Haywood¹ is that the order of velocities may depend on the temperature chosen for their measurements if their temperature coefficients are unequal. Haywood endeavoured to get over this difficulty by measuring the ratio of the velocities under condition of equal entropy change i. e., where Q/T was constant and found that under these conditions the velocity ratios were constant. This result however follows at once from the fact that Q is calculated from the ordinary equation $d \log k/dt = Q/RT^2$. Haywood's results have been criticised on other grounds.²

If by the reactivity is meant the ease with which a compound may be brought to the reactive state or activated condition then it is difficult to resist the conclusion that energies of activation or some quantity closely connected with them are the true measure of this property. The theories which have been brought forward to explanation in varying reactivity suffer no distortion if the above meaning is attached to the term but may perhaps be considered to acquire a greater degree of precision. Energies of activations are less susceptible of accurate comparison than velocities of reaction but the latter quantities seem made up of two factors, only one of which can be easily seen to depend on structure.

Several equations have been suggested for expressing the velocity of a bimolecular reaction in terms of other molecular constants. Dushman³ suggests the equation:

$$k = N\sigma^2 \sqrt{8\pi RT} (1/M_A + 1/M_B) \sqrt{e^{-(Q_A + Q_B)/RT}}$$

or $k = e^{-Q/RT}$

If we restrict ourselves to reactions such as those between aniline and m or p nitrobenzyl chloride then M_A and M_B will be the same in the two cases and the values of σ will probably also be very close. The same remarks apply to all reactions in which m and p isomers are compared with a fixed reactant. If then the velocities for such a pair of reactants be compared at equal temperatures we have:

$$\log_e k_p = \log_e A_p - Q_p/RT$$

and $\log_e k_m = \log_e A_m - Q_m/RT$

If $A_m = A_p$ as assumed above, then $\log_e k_p - \log_e k_m = 1/RT (Q_m - Q_p)$ or $RT \log_e k_p/k_m = Q_m - Q_p$.

where Q_m = sum of the energies of activation for the fixed reactant A , and the m isomer i. e. $Q_m = Q'_A + Q'_m$ and so with Q_p .

In Table V are collected values for $RT \log_e k_p/k_m$ and of $Q_m - Q_p$ for several reactions; the hydrolysis of substituted benzyl chlorides was studied by Holleman (loc. cit.) the other results are by the present author.

(c) Benzyl chloride $T = 308^\circ$

<i>m</i> - and <i>p</i> -dimethyl toluidine	0.1424	201	1380
---	--------	-----	------

The lack of agreement between the values of $RT \ln k_p/k_m$ and $Q_m - Q_p$ may indicate either experimental error in the determinations or lack of equality between A_m and A_p . Certain interesting relationships appear however when the results are examined and it is proposed to study these more fully. The ratio k_m/k_p for *o*-toluidine is practically equal to that for *p*-toluidine while that for dimethyl aniline is practically equal to that for ethyl methyl aniline. This indicates that for each reaction $A_m = A_p$ and also that $Q_m = Q'_A + Q'_m$. Therefore, $Q_m - Q_p = Q'_m - Q'_p$, constant as long as the *m* and *p* isomers react with substances of similar constitution.

A strict comparison between chlorine, bromine, and iodine compounds cannot be made because all the necessary data are not known but the results of Conrad and Bruckner (loc. cit.) show that with alkyl oxides the temperature coefficients of the reaction velocities are approximately equal while the actual velocities vary very greatly; thus there is a greater discrepancy be-

tween the values of E_1/E_2 and $\frac{\log k_1}{\log k_2}$ than would be expected from the varia-

tion in σ and molecular weight in passing from one halogen compound to another. A reference to the discussion of the reaction velocities of chlorine, bromine and iodine compounds with amines and with sodium thiosulphate shows that here also the velocity constant show much greater variation in value than is shown by the energies of activation. Energies of activation like heats of combustion and ionisation potentials show only small changes in passing from chloro to bromo and iodo compounds.

It therefore follows that the equation for a bimolecular reaction is of the type: $k = k_1 e^{-Q/RT}$ where k_1 is a constant much more dependent on the

constitution of the compounds concerned than the expression involving molecular diameters and molecular weights. Perrin and Job suggest that this term represents the sensibility or ease of activation of the molecules.

It is also possible that k_1 represents some function of the stability of the activated molecule. The high rates of reaction frequently observed with iodo compounds may then be due mainly to the longer life of the activated molecules of the iodo compound as compared with those of a bromo or chloro compound. Similarly the very much greater reactivity of *o*- or *p*-nitro bromo benzene as compared with *m* nitro brom benzene may be ascribed not entirely to an alternating effect on the energy of activation but also to an effect on the stability of the activated state. It is also possible that the effect of the solvent on reaction velocity may be partly due to the same cause.

A comparison of reaction velocities or what is the same thing of the quantities of isomers formed in a particular reaction thus involves two quantities at least, the energy of activation and another quantity which may be the sensibility to activation, the stability of the activated molecule or a combination of both.

Summary

(1) Attention is drawn to the alternating effect of substituents upon the energy of activation for the reactions studied.

(2) The effect of energy of activation in altering the ratios of velocities and therefore the ratios of the products formed, at different temperatures is pointed out.

(3) It is suggested that the alteration in activation energy is a more truthful expression of the effect of substituents upon reactivity than is the velocity of the reaction.

(4) A comparison is made of the effect of substituting one halogen for another upon the velocity constant and energy of activation for a number of reactions. The order of energies of activation is compared with the order of ionisation potentials for the halogen acids.

(5) Velocities of reaction are affected not only by alterations in activation energy but also by variations in the sensibility of the molecule (Perrin, Job) and the stability of the activated state.

(6) The applicability of Dushman's equation to the cases concerned is examined.

THE EFFECT OF HIGHER ALIPHATIC ACIDS ON THE SURFACE TENSION OF A HEAVY HYDROCARBON OIL*

BY E. C. GILBERT

The surface tensions of solutions of fatty acids in aliphatic and aromatic hydrocarbons both at liquid-vapor and liquid-liquid interfaces have been reported by various investigators¹ but little is known concerning the longer chain acids and the heavier hydrocarbons. The present study was initiated because of its bearing on the effect of small quantities of fatty acids on the properties of lubricating oils.

Materials

For the hydrocarbon "Liquid Petrolatum Squibb" was chosen. It is described as a pure naphthene from California crude. It had no odor, and practically no water content (as shown by placing freshly cut sodium in it). It contained no paraffin or sulfur compounds and possessed a density at 20°C, of 0.8845. It was of course chemically a mixture. "Nujol," described as a pure paraffin oil, would have been preferable to a naphthene from a theoretical standpoint but the Nujol available showed a higher water content. The surface tensions and solubility relationships were very similar as shown by preliminary investigation not reported, so the Squibb's oil was used thruout.

The fatty acids used were myristic, $C_{14}H_{28}O_2$, M.P. 52°-53°, and pelargonic, $C_9H_{18}O_2$, M.P. 10°-12°, the latter being a liquid at ordinary temperatures. Both were obtained from the Eastman Kodak Co. The myristic acid was quite soluble in the hydrocarbon at higher temperatures but not very soluble at 20° (considerably less than 0.4 mols per 1000 g.). The pelargonic acid was miscible in much higher proportions.

Procedure

A series of dilute solutions of each acid was made up by weight, using a stock solution containing 0.371 mols per 1000g. as a source of myristic acid, and by direct addition of the liquid pelargonic acid. These solutions were made and preserved in flat glass stoppered bottles of 5-6 cm. diameter. After the acid was added the solutions were heated to 120°C. in an oven and well stirred to secure even mixing. They were then allowed to cool down overnight in a large room of very constant temperature. Care was taken to have all apparatus scrupulously clean. Densities of the solutions of highest and lowest concentration were determined by the use of a pycnometer, and for intermediate concentrations were interpolated.

The surface tensions were determined by the use of the du Noüy tensiometer² which had been calibrated against water, benzene, and bromobenzene by the recently published method of Harkins, Young, and Cheng.³ The

ratio, radius of ring to radius of wire in the ring, was 32.02. The radii were measured carefully with a travelling microscope. The apparatus was tested to see that the torsion was proportional to the pull on the ring. The graph was a straight line. A long, rigid, pointed wire was affixed to the beam, opposite to which was another sharply pointed wire adjusted so that at the zero reading of the instrument the two points coincided. This aided materially in maintaining the beam in zero position as the movement of the beam was

FIG. 1

magnified. The instrument was always adjusted for the zero point with the ring wet. The readings were readily duplicated and the absolute values are believed to be accurate to $\pm 1\%$, the relative readings being more accurate than that. For the pure Squibb's oil at 20° a value of 31.23 dynes per cm. was obtained. A value of 31.12 was reported for a sample of similar Squibb's oil in 1922, using the very accurate drop-weight method.¹ A large vacant room was used and the constancy of temperature was such that a constant temperature bath was not required.

Without the precautions and corrections made as directed by Harkins and his collaborators the ring method gives results much too high. For the Squibb's oil the apparent surface tension by this method was 34.60 dynes. The corrections are somewhat lengthy of explanation and the reader is referred to the original article.

Results

The results are tabulated in Table I. The surface tensions were plotted against logarithm of the concentration in Fig. 1, and the adsorption of the acid on the surface of the hydrocarbon calculated from the equation of Gibbs, $U = -1/RT \cdot \delta \gamma / \delta \ln C$. When $\delta \gamma / \delta \ln C$ becomes constant it is com-

¹ Harkins and Feldman: J. Am. Chem. Soc., 44, 2665 (1922).

monly assumed that the surface has become covered with a layer of the solute one molecule thick¹ and on this basis the area covered by each molecule was calculated.

Discussion

The curves for the two acids, surface tension-log C are very similar to each other. The pelargonic acid, being more soluble, gives correspondingly less lowering of the surface tension for the same concentration. Both curves follow the general form observed when the solute lowers the surface tension of the solvent and is positively adsorbed in the surface, but both are characterized by a sudden change in the slope of the curve when only a relatively small lowering of the surface tension has occurred. Beyond a concentration of 0.06-0.08 M there is only a lowering of less than 0.3 dyne for a 10-fold change in the concentration in the case of pelargonic acid, and the flattening of the curve for myristic acid begins even at a concentration of 0.02 M. This sudden change of slope occurs just after the surface has been covered by the monomolecular layer. The sudden flattening of the curve therefore seems to indicate that beyond this point of saturation of the surface layer the surface tension observed is predominantly that of the material in the surface rather than that of the solvent. The actual total lowering is rather small, only one dyne at the most, for the concentrations observed. This in marked contrast to the behavior of water but is due to the fact that the surface tension of the acids is not far below that of the oil.

¹ Langmuir: J. Am. Chem. Soc., 39, 1848 (1917).

The question of the orientation of the molecules in the surface layer is interesting in this case since we have a situation just reversed from that of the fatty acids in water. Here in this experiment we should expect the long hydrocarbon chains of the acids to be soluble in the body of the solvent and the polar carboxyl groups forced to the surface. In the case of myristic acid the slope $\delta\gamma/\delta \log C$ becomes constant at $C = 0.0083$ M and remains so approximately to $C = 0.02$ M. In this range $U = 0.15 \times 10^{-10}$. Assuming a density at 20° of 0.88 ($d = 0.858$ at 60° C.) this gives a thickness of only 0.4×10^{-8} cm. for the surface layer and an area of 11×10^{-14} cm.² per molecule. These are sufficiently far from the data of Langmuir to indicate that here the similarity between solute and solvent is so great that each solute molecule may have associated with it a number of solvent molecules. This is supposed to be the case with acetic acid and water where the dimensions of molecules calculated from surface tensions are at variance with those expected.¹

With pelargonic acid the surface layer is saturated only at a higher concentration ($C = 0.014$ M) due to greater solubility; $U = 0.13 \times 10^{-10}$, and the calculated thickness only 0.22×10^{-8} cm.

If the molecules are assumed to lie on their side in the surface the observed dimensions are not so far from the expected, as then the calculated thickness would be of the order of 4×10^{-8} cm. It is more than likely that such is the case, but there still are not enough acid molecules to cover the surface, completely excluding all solvent molecules.

Summary

The surface tensions of solutions of pelargonic and myristic acid in a pure heavy hydrocarbon oil have been determined by the ring method, as modified by Harkins.

From these the adsorption of the acids on the surface of the oil has been calculated, also the apparent thickness of the surface layer and the area per molecule.

The surface tension dropped quite rapidly at small concentrations until shortly after the surface layer became saturated, beyond which point increased concentration had an extremely small effect.

The calculated thickness is too small and the area too great indicating that probably the molecules of solute and solvent are sufficiently similar so that solvent molecules are not completely excluded from the surface.

Cornwallis, Oregon.

THE ELECTRICAL CONDUCTIVITIES OF SOME SOLUTIONS IN ANILINE

BY JAMES ROBERT POUND

Frequently the electrical conductivities of non-aqueous solutions are of a different order of magnitude to those of aqueous solutions. Also often the former vary with the concentrations of the solutions in a different manner to the well-known behaviour of aqueous solutions; in the latter solutions the equivalent conductivity, A , rises as the concentration decreases and reaches a more or less definite maximum, A_0 , but in many non-aqueous solutions the equivalent conductivity falls as the concentration decreases and approaches the value zero at zero concentration.¹ The present paper deals chiefly with the electrical conductivities of some solutions in aniline at 30°.

Qualitative Experiments. Two platinum wires were connected through an electric lamp to the city 220 volt D.C. supply. The wires were placed about half a centimetre apart in various solutions in aniline; and when the current was turned on, the effects were noted. With a few of the best conducting solutions the lamp lit up. In the conducting solutions there was evolution of gas (hydrogen?) at the cathode with more or less rapidity, and at the anode a dark brown solution appeared and slowly mixed with the bulk of the liquid, which was usually of a light brown colour. These two effects were taken as indications of the conducting power of the solution. If a solution was a poor conductor and gave no gaseous products on electrolysis, then these experiments would fail to indicate its conducting power. The solutions were of indefinite strength; but if the solute was not very soluble they were saturated. The experiments were done cold and then hot—up to the boiling point of aniline. The aniline was distilled pure aniline (v. later), and the solutes were the best commercial products, taken as dry, which certainly was the case with most of them. The presence of water usually increased the conducting power. The solubilities of the solutes varied greatly. More than one hundred substances were tested in this manner.

Conducting solutions with aniline were given by the acids and their anhydrides and by the salts of organic bases (if these substances were at all soluble). Such were acetic acid, acetic anhydride, phthalic acid, phthalic anhydride, salicylic acid, phenylacetic acid, succinic, picric, hippuric, sulphosalicylic, sulphanilic and other sulphonic acids, monochloroacetic acid, rosolic and pararosolic acids; aniline hydrochloride, *m*-phenylenediamine hydrochloride, 'methyl violet' or pentamethylpararosaniline hydrochloride, and similar salts, and saccharin. The conductivities of the first six substances and of aniline hydrochloride and saccharin were investigated quantitatively (v. later), as also were the conductivities of benzoic acid in aniline. Benzoic

¹ C. A. Kraus: "The Properties of Electrically Conducting Systems" (1922); Pound: J. Chem. Soc., 99 (1911); 121 (1922); 125 (1924).

acid, though freely soluble in aniline, gives very poorly conducting solutions, which in these qualitative experiments were classed as non-conducting; thus some of the following non-conducting solutions may be similar to those of benzoic acid. The stronger an acid, the better conducting is its solution in aniline, unless it forms anilides which give poorly conducting solutions (v. later). The salts (hydrochlorides) of complex bases, like methyl violet, seem to give poorer conducting solutions than the salts of simpler bases; but this may be largely due to their differing solubilities.

The substances that gave non-conducting solutions with aniline were (1) most salts, e.g. potassium cyanate, sodium oxalate, quinine sulphate, aniline sulphate, calomel and zinc valerianate. Most of these salts were very sparingly soluble. (Mercuric chloride is not very soluble in cold aniline; but, on warming, the mixture suddenly turns dark and gives a purple solution or suspension, which with the application of the electric current heats and boils and certainly conducts to an appreciable extent.) It may be noted that many of the suspensions in aniline show appreciable cataphoresis. (2) Alcohols, phenols and their salts, aldehydes, ketones, esters and ethers, e.g. phenyl-ethyl-alcohol, β -naphthol, phenol and potassium carbolate, acetone, acetophenone, salol, methyl-benzoate, anethole and ethyl ether. Some of these substances are said to unite with aniline¹; but the compound- or complex-formation evidently does not give any appreciable conductivity. (3) Free bases, hydrocarbons, organic chlorides, etc., e.g. urea, m-phenylenediamine, quinine, benzene, iodoform and chlorobenzene.

These "non-conducting" solutions are certainly of varying electrical conductivities. Thus the weak acids, like benzoic, camphoric, cinnamic, anthranilic and anisic acids, were included here, though they differ only in degree from the stronger acids that give appreciably conducting solutions. Again, acetanilide is fairly soluble in aniline; its solution was classed as non-conducting; a quantitative measure of its conductivity is given later.

Quantitative Experiments. All the materials were purified and dried and were kept in desiccators throughout. The aniline was kept for long periods over solid caustic potash, and then distilled; only the middle fractions of constant boiling point were used, and these were of pale yellow colour. The electrical conductivities at 30° of the samples of aniline varied from 0.000, 000,029 to 0.000,000,020 ohm-cm. units; the former samples are most likely to contain traces of water, the latter to contain higher homologues of aniline. Their densities at 30° varied from 1.01292 to 1.01336. One sample of aniline initially had $k = .07206^\circ$ and $D_4^{30^\circ} = 1.01336$; this was 48 days after distillation; when finishing work with this sample 60 days later, i.e. 108 days after distillation, it was found that $k = .07273$ and $D_4^{30^\circ} = 1.01332$. Thus in two months the density had scarcely changed and the conductivity had increased by .087, not an appreciable amount and possibly an extreme value as the other samples of aniline were used up more quickly than this one. This increase of conductivity was probably due to absorption of traces of

¹ Oddo and Tognacchini: J. Chem. Soc., 124 I, 224 (1923).

water. The electrical conductivities of the solutions, as given in the tables, are all "corrected" for the conductivity of the aniline (solvent); that is, the figures in the tables are the conductivities of the solutions *as found* minus that of the solvent, which latter is shown in the table underneath the figures corrected thereby.

The conductivity measurements were made by the usual Kohlrausch (Wheatstone bridge) method. Wireless head-phones, each of a resistance of 2000 ohms, were found to be better than low-resistance telephones. The resistances of the cells containing the solutions were from 50 to 300,000 ohms, excepting with some extreme cases and with the aniline alone. Two electrolytic cells were used; their "cell-constants" were .1072 and .03415. The latter values were found by standardisation at 30° with N/100 (18°) potassium chloride solution, carefully made from the purified salt and water, and assumed to have at 30° $k = 0.001,552$ plus the k of the water, which was 0.000,003. In standardising these cells with this dilute potassium chloride solution care was necessary to avoid bubbles forming on the electrodes; by exhausting the air from the stock bottle of the solution for some time before using, this trouble could be minimised. The average error in the determination of the resistance of a cell full of electrolyte was $\pm 0.32\%$. The error was somewhat greater when the cell resistance was over 150,000 ohms. It is well known, however, that in this work larger errors may occur between different or duplicate experiments. In the tables there are given with each solute the independent figures of at least two series of experiments. The cells were placed in a thermostat kept within one or two hundredths of a degree of 30°, using a standardised thermometer. While a solution was in the conductivity cell, there was often a slight tendency for the conductivity to increase, say, by 1 to 5 parts in 1000; this may be due to better contact at the electrodes after slight passage of current. When the solutions in aniline had a lower conductivity than 0.000,001, the error of experiment increases, the influence of traces of moisture and of other disturbing impurities becomes greater, and the conductivity of the aniline itself (or the 'blank' which is subtracted from the observed conductivity to give the value quoted) becomes relatively large; for such solutions therefore the total errors are liable to be large.

The mixtures were all made up by weight in well-stoppered weighing bottles, which were kept in desiccators over calcium chloride or sulphuric acid as much as possible. One mixture was made up from solute and solvent; part was used for the determination of the electrical conductivity or density, and the remainder was diluted with further solvent to give a new solution. The parent solutions of a series are denoted in the tables by an asterisk (*) after the percentage of solute. The densities (30°/4°) of certain solutions were determined with all precautions, and thus the concentrations in gram-molecules per litre at 30° of all the solutions could be determined, since the density-percentage weight curves for these dilute solutions were practically straight lines.

(1) *Solutions of Acetic Acid in Aniline.*

A study of the density, viscosity and electrical conductivity of mixtures of acetic acid and aniline was completed in this laboratory¹ in 1923; but the whole field of possible mixtures of these substances, with and without water, was then covered. The present work was done with more dilute solutions of the anhydrous liquids. The acetic acid, which had been previously purified, was traced with phosphorus pentoxide, filtered off and distilled, and the middle fraction, B.P. = 119.0–119.5°, was collected. The electrical conductivities of these solutions showed no signs of altering on keeping. The acetic acid concentrations in gram-molecules per litre at 30° were calculated from the percentage weights of acid and from the densities obtained from the 1924 data, from which source we had the following results:—

Densities and Viscosities of Solutions of Acetic Acid in

Aniline at 30° in C.G.S. Units:—

% wt. of acid	Density	Viscosity
16.375	1.0284	.0450
8.1905	1.0202	.0366
2.8880	1.0154	.0336
1.6234	1.0144	.0328
0	1.0131	.03226

With monochloroacetic acid dissolved in aniline the conductivity of the solution rapidly increased with time; e.g. with a solution of 0.9% monochloroacetic acid in aniline the initial specific conductivity at 30° was about 0.000,002, and this more than doubled after 24 hours' keeping at 10°. Thus the solution of such a strong acid in aniline is not in equilibrium. With the above solution, crystals (the anilide?) appeared throughout the mixture after half an hour, but these disappeared after two days and then the solution became red-brown, the colour deepening with time and hydrochloride accumulating in the solution.

(2) *Solutions of Aniline in Acetic Acid.*

The same materials were used as in (1). These mixtures, when first made, had a slight pink colour; this rapidly faded to a straw colour and on further dilution with the acid became colourless. Here with the mixtures containing small percentages of aniline, i.e. with 2% aniline or less, the electrical conductivity decreased with time, the rate of decrease being greater at 30° than at room temperature (10° to 20°), and consequently these results, marked §, are but approximate. In any experiment where the electrical conductivity was found to vary, the initial values are given in the tables. With mixture 39 the conductivity decreased to half the original value after 24 hours at room temperature, 20°, though with mixture 38 no decrease in conductivity was noticed. With mixture 44 the conductivity decreased by 0.35% while the determination was being made, i.e. within 1/4 hour at 30°, and by 22% after 4 hours at 25°. This decrease in conductivity with time is probably connected with the action of the aniline and the acetic acid to form acetanilide and

¹ Pound and Russell: J. Chem. Soc., 125, 769; Pound: 1560 (1924).

water; this action is faster probably in acetic acid solution than in aniline solution; the acetanilide forms poor conducting solutions in both these solvents (pp. 551, 552). However water is formed at the same time by this condensation, and this would tend to make the solutions better conductors. Thus the change in the conductivity of aniline dissolved in acetic acid will not be simple; and it might happen that the same action, which would produce a decrease in conductivity in dilute solutions, might produce an increase in conductivity in more concentrated solutions. The 1923 results with aniline in acetic acid are higher than these results but parallel to them. The present results are the better, the liquids being purer and drier. It might be noted that the conductivity of the acetic acid more than doubled during the course of the experiments over the period of one month; but the last of these experiments, 42 to 44, were done three weeks after the previous three series. This increase in conductivity is certainly due to the absorption of traces of water. The densities and viscosities of these solutions were taken from the 1923 data, e.g.:—

% wt. Aniline	Density (30°/4°)	Viscosity (30°)
28.693	1.08426	0.1371
21.010	1.08125	————
10.729	1.0661	————
5.259	1.05313	————
0	1.03779	0.01031

(3) *Solutions of Acetic Anhydride in Aniline.*

The acetic anhydride was prepared from May and Baker's "Acetic Anhydride". Sample (1) used in experiments 46 to 51, was obtained by shaking the original with phosphorus pentoxide for some minutes, filtering and distilling. The collected distillate was the last third and had B.P. = 137.0–139.4°; its conductivity at 30° was 0.000,001,77. Sample (2) of acetic anhydride, used in experiments 54 to 58, was obtained by treating May and Baker's liquid with sodium at room temperatures for 48 hours, filtering off from the sodium acetate, shaking with phosphorus pentoxide for some minutes, filtering and distilling. The collected distillate had B.P. = 137.7–139.2°, and its conductivity at 30° was 0.000,002,765. These comparatively high values for the electrical conductivity of the acetic anhydride probably indicate the presence of some acetic acid, even though the second method of purification is supposed to be efficient.¹

Aniline and acetic anhydride mix with evolution of heat, and the mixtures are good conductors. A mixture of approximately equal volumes of these two liquids is quite viscous when it cools to room temperatures, and from the solution crystals (acetanilide) readily separate. Such a mixture containing 39.42% wt. of acetic anhydride had at 30° the conductivity of 0.000,573 approximately, indicating that the conductivity-composition curve for these mixtures is similar to that for acetic acid-aniline mixtures, where the conductivity rises to a maximum for some mixture of intermediate composition.

¹ Walton and Withrow: J. Chem. Soc., 126 II, 209 (1924).

With dilute solutions of aniline in acetic anhydride the electrical conductivities decrease rapidly with time; e.g. a solution with 5.7% wt. of aniline had a conductivity of 0.000,004,41, and its conductivity decreased by 8% in 1/4 hour at 30°. The acetic anhydride alone had $k = 0.000,002,76$, so that the initial 'net' conductivity of the solution was 0.000,001,65. Such solutions in a solvent which itself is of high conductivity are unsuited for study. Solutions of acetanilide in acetic anhydride also gave conductivities decreasing with time; e.g. a 10.375% solution of acetanilide in the above acetic anhydride gave $k = 0.000,005,46$, decreasing by 1.3% in 1/4 hour at 30°; the initial 'net' conductivity is thus 0.000,002,70. Probably aniline in acetic anhydride quickly gives acetanilide and acetic acid, and then more slowly diacetanilide is formed.

With dilute solutions of acetic anhydride in aniline the conductivities do not vary too quickly with the time, and a consistent set of values may be obtained. However the general tendency is for the conductivities of these mixtures to increase with the time; e.g. with mixtures 47, 49, 51 and 58 the conductivities increased by 1.2, 1.5, 6.0 and 27% after 164, 144, 101 and 768 hours' keeping at room temperatures respectively. The rate and the proportional amount of increase of conductivity are the greatest for the most dilute solutions, the last example being the extreme case observed. The probable chemical actions, when the aniline is in excess, are:—

Action (2) must be much slower than action (1); thus with solutions of acetic acid in excess of aniline no evidence of change of conductivity was noticed during the experiments, though doubtless it would occur after keeping for days. The tables show that the acetic anhydride gives a better conducting solution with aniline than the acetic acid and acetanilide derived from it would give, adding the conductivities due to the latter substances together; either then the effect of the last two substances together, with or without unchanged acetic anhydride, is not additive, or traces of water from action (2) are rapidly formed, or other actions must be taken into account. Probably additive compounds are first formed between the solvent and solute; and their ionisation determines the initial conductivity, and their subsequent changes the changes of conductivity. Solutions of acetic anhydride in aniline are better conductors than solutions of acetic acid in aniline, comparing either equi-molecular solutions or equivalent solutions above 0.75 normal; below 0.75 normal the solutions of acetic acid are the better conductors. But solutions of phthalic acid are better conductors than equi-molecular solutions of phthalic anhydride in aniline (v. later).

The following densities were obtained for solutions of acetic anhydride, sample (1), in aniline:—

% wt. of acetic anhydride anhydride	Density (30°/4°)
9.4506	1.02808
4.9140	1.02099
100	1.06670
0 (Aniline)	1.01292

Also a solution of acetanilide in aniline, containing 4.7363% of acetanilide, had at 30° the (net) specific conductivity of 0.000,000,101.

(4) *Solutions of Phthalic Anhydride in Aniline.*

May and Baker's well-crystallised phthalic anhydride was kept in an exhausted desiccator over sulphuric acid for several days before making the solution in aniline. Solution was effected by gentle warming, say at 50°, except that mixture 68 was prepared in the cold, requiring six days at about 12°. Mixture 68a is about saturated at room temperatures. Aniline and phthalic acid condense and form phthalanilic acid, $\text{Ph.NH.CO.C}_6\text{H}_4.\text{CO.OH}$, then phthalanilide, $(\text{Ph.NH.CO})_2\text{C}_6\text{H}_4$, and then phthalanil,

$\text{PhN} \begin{array}{c} \diagup \text{CO} \\ \diagdown \text{CO} \end{array} \text{C}_6\text{H}_4$; the first compound¹ is formed in twenty minutes at ordinary temperatures. From a solution of phthalic anhydride in aniline, that has been heated to the boiling point, crystals separate on cooling. The various solutions of phthalic anhydride in aniline gave moderately consistent values for their conductivities, which too were unaltered after keeping twelve days at room temperatures. The following densities were determined:—

% Phthalic anhydride	Density (30°/4°)
4.997	1.03194
0.7305	1.01542
0	1.01292

(5) *Solutions of Phthalic Acid in Aniline.*

Merck's crystalline phthalic acid was dried over calcium chloride and dissolved by gentle warming in the aniline. It did not dissolve readily. Its solubility was small; the solution with 0.5% of phthalic acid slowly became turbid even at 30°. This solution had at 30° the density of 1.01496, while the aniline had density of 1.01321. With solution 77, the conductivity had increased by 1% after keeping for 5 days; in other experiments the increase of conductivity with time was similarly slight.

(6) *Solutions of Phenyl-acetic Acid in Aniline.*

Solutions of well-crystallised phenyl-acetic acid were prepared as with the preceding solids. The 10% solution was about saturated at 13°. The conductivities were low, and they increased with the time of keeping in the cell at 30° by 1% or more in 1/4 hour. The accuracy of the determinations is therefore moderate; the conductivities of mixtures 82 and 83 are higher than those of the others. The solution with 10.034% of phenyl-acetic acid had at 30° the density of 1.02569, while the aniline had the density of 1.01292.

¹ Tingle and Cram: *Am. Chem. J.*, 37, 596 (1907).

(7) *Solutions of Salicylic Acid in Aniline.*

These solutions were made from the dried Merck's pure salicylic acid and aniline by gentle warming. The solubility was low. The conductivities were low, and increased somewhat with time—similar to those of the phenyl-acetic acid solutions. The mixture 89 was kept in the desiccator at room temperatures for 11 days before determining its conductivity, but the result seems quite a normal one. The densities of these dilute solutions were assumed from those of similar dilute solutions of phenyl-acetic acid and benzoic acid.

(8) *Solutions of Benzoic Acid in Aniline.*

Howard's sublimed benzoic acid was dried in an exhausted desiccator over sulphuric acid for several days. The solutions were usually made with the aid of gentle warming. Mixture 141 was made in the cold (12°) from the same benzoic acid after resubliming; it took 4 days to dissolve. The mixtures containing much benzoic acid, say 10% and over, were appreciably more viscous than the original aniline. The mixture with 18% benzoic acid solidified on standing at 10°; the crystals were probably some aniline benzoate.¹ The following densities were determined:—

% benzoic acid	Density (30°/4°)
14.888	1.03685
8.676	1.02677
5.0515	1.02100
1.988	1.01625
0	1.01315

The ready solubility of benzoic acid in aniline permits the examination of many mixtures, but unfortunately the electrical conductivities are so low that the experimental errors and the influence of probable impurities, say the slightest traces of water, are large. The lowest results—presumably the most accurate—are those with mixture 141 (v. above) and mixture 142, which was made by diluting the former with aniline. Mixtures 100 to 104 gave higher conductivities which were neglected.

(9) *Solutions of Aniline Hydrochloride in Aniline.*

Aniline sulphate is not at all soluble even in boiling aniline, and the solution does not conduct appreciably; the concentration of the dissolved salt is probably less than 0.05%. Aniline hydrochloride, however, is appreciably soluble in aniline; the mixture 135 with 6.38% of aniline-hydrochloride solidified entirely on keeping for an hour or so at 13°; the solid may be some compound² like 2 An., HCl. The solutions of aniline hydrochloride in aniline are relatively good conductors. There was little or no tendency for the conductivity of these solutions to vary with time; e.g. after 8 days the conductivity of mixture 134, $k \times 10^6 = 17.55$, had decreased by less than 0.4%, though the mixture had become a little darker in colour. Merck's pure aniline hydrochloride was used after drying in an desiccator over sulphuric acid for several

¹ Berthelot: J. Chem. Soc., 53, 1361 (1890).

² Mandal: J. Chem. Soc., 120 I, 106 (1921).

days. Mixture 133 was made in two days at room temperature, about 20°, but the other parent mixtures were made by gentle warming. The following densities were found:—

% wt. of aniline hydrochloride	Density (30°/4°)
6.3836	1.02527
4.3978	1.02159
0.8205	1.01475
0.2690	1.01366
0	1.01300

Mixtures 133 and 134 gave higher conductivities than the others and are not quoted in the tables. Mixtures 135 to 140, the third series, tend to have lower conductivities than the mixtures of the first two series and are probably the most accurate. The concentration of the aniline hydrochloride in gram-molecules per litre is, of course, also the concentration of hydrochloric acid, assuming that the acid were dissolved in the aniline and subsequently combined with it. Subsequently we shall often refer to these solutions as solutions of hydrochloric acid in aniline.

(10) *Solutions of Saccharin in Aniline.*

Saccharin, o-sulpho-benzimide, is easily soluble in warm aniline, and the solutions are relatively good conductors. The best commercial saccharin was dried in an exhausted desiccator over sulphuric acid, and the solutions were made by gentle warming. Saccharin from two different sources was used with no difference in the results; e.g. mixtures 105 to 108, 120, and 121 to 124 were made with sample (1) saccharin; mixtures 113 to 119 were made with this saccharin after sublimation; mixtures 109 to 111 were made with sample (2) saccharin. The parent mixtures 113, 120 and 121 were made in the cold within 24 hours. The conductivities of mixtures 113 and its derivatives were slightly higher than those of the other mixtures; this may be due to the sublimed saccharin being the purest. The mixtures tend to become browner on keeping. Mixtures 105 to 111 were done with one sample of aniline, and mixtures 113 to 124 with another. The conductivities of these mixtures decreased very slightly with time, e.g. the conductivity of 108 decreased by 1% after 6 days. Mixture 116 was made from 114 after a lapse of 11 days. The following densities were determined:—

% wt. of Saccharin	Density (30°/4°)
8.2631	1.04760

Discussion of the Results

Here we refer to the concentrations of the solutes, c , in gram-molecules per litre at 30° , the specific conductivities, k , in ohm-cm. units, and the molecular conductivities, A or k/c . The specific conductivity-concentration curves, k - c curves, Fig. 1, are in general concave to the k axis, and their

FIG. 1

'steepness' increases with c . Of course, with completely miscible solutes, like acetic acid in aniline, at high concentrations the curve has a point of inflexion, bends and reaches a maximum, and thence descends towards the c -axis once more; but we are not concerned with these concentrated solutions here. With our dilute solutions the k - c curves are, in general, concave towards the k -axis throughout, and so that for a certain range of concentration k is, with more or less accuracy, proportional to c , then for a higher range of concentrations proportional to c^2 , then to c^3 , and so on. At low concentrations, $c = 0$ to 0.1 approximately, we have $k \propto c$, or the k - c graph a straight line, for saccharin, hydrochloric acid (aniline hydrochloride), phthalic acid, phthalic anhydride and salicylic acid in aniline. The k - c straight lines for these solutions do not go through the origin ($0,0$), but at zero concentration indicate $k \times 10^6 = 0.3$ approximately. However the behaviour in extremely dilute solutions must be determined by more accurate experiments. With the other five solutions the curve is concave throughout and also apparently goes to the origin. The k - c curve probably goes to the origin for salicylic and phthalic acids also. The k - c curves for the last two substances show a resemblance to the k -

curves for solutions of electrolytes in water (v. later). In general the k - c curves do not cross. The order of the curves for the solutions in aniline is as follows, proceeding from the solutions of lowest to those of highest conductivity:—Benzoic acid, phenylacetic acid, acetic acid, acetic anhydride, phthalic anhydride, salicylic acid, saccharin, hydrochloric acid (aniline hydrochloride), and phthalic acid. Comparative values for the specific conductivities are given below. (The curves for hydrochloric acid and saccharin cross at $c = 0.3$; and the phthalic anhydride curve at low concentrations cuts the salicylic acid curve, but this part of the phthalic acid curve is perhaps abnormal.)

In general, the molecular conductivity, A , rises increasingly rapidly with increasing concentration. At low concentrations, $c = .05$ to $.1$, A often reaches a minimum, and then at lower concentrations A rises with decreasing

concentration; such is the case with the aniline hydrochloride and saccharin solutions. With phthalic and salicylic acids we can deal only with low concentrations, and here throughout the A-c curves fall with increasing concentration. Thus with these two acids dissolved in aniline we have an approach to the behaviour of weak electrolytes, like acetic acid, in aqueous solutions. There is, however, no definite limiting molecular conductivity at zero concentration, as the A-c curve is asymptotic to the A-axis. For the curves that rise to some value of A_0 , however indefinite, at zero concentration we have the following more or less probable values of A:—phthalic acid, 400–600; saccharin, 160; hydrochloric acid, 160; salicylic acid, 50. With phthalic anhydride and benzoic acid the A-c curve is doubtful at low concentrations; the experimental errors are here too large. With the other solutions the A-c curve, in the absence of more accurate data, falls throughout to the limiting values,—for acetic acid, 0.35; acetic anhydride, 0.5; phenylacetic acid, 0.45; and for aniline in acetic acid probably zero. In these solutions, for which A falls with decreasing concentration, the nature of the ionisation, etc., must be vastly different from the conditions holding in aqueous solutions. Also in the former solutions the significance of A_0 , if it is other than zero, must be different from that usually accepted for A_0 in aqueous solutions, where the maximum value, A_0 , is held to indicate complete ionisation.

We endeavoured to see whether the mass-action law held for these solutions. If we suppose a binary electrolyte, ionising as $AB \rightleftharpoons A^+ + B^-$, and let c = the concentration of the original electrolyte AB and γ = the degree of ionisation, then if the mass-action law holds $k_1c(1 - \gamma) = k_2c^2\gamma^2$. In the usual consideration of aqueous solutions we put $\gamma = A/A_0$, and deduce that $1/A = (1/aA_0^2)(CA) + 1/A_0$, where a = the ionisation constant = k_1/k_2 ; whence $1/A$ is a linear function of (CA) or k (the specific conductivity). It is, however, not necessary to consider the value of A_0 in order to test this relationship. For k is proportional to c , the ion concentration, or $\gamma = k/dc$,

where d is a constant; then the mass-action equation leads to $\frac{k^2}{d(dc - k)} =$

the ionisation constant, a ; whence $\frac{c}{k} = \frac{1}{ad^2}k + \frac{1}{d}$, which is the same relation

as found before. It is necessary to note this, for in the present solutions the functions A_0 and A/A_0 have little or no significance. We have tested the agreement of our data with this equation. We find that for aniline in acetic acid and for acetic acid, acetic anhydride and phenylacetic acid in aniline the c/k — k curve is hyperbolic and asymptotic to both axes. For phthalic and salicylic acids in aniline this curve is concave to the k -axis and approaches the c/k axis asymptotically; probably here the mass-action law holds approximately for very dilute solutions. With hydrochloric acid and saccharin in aniline the curve is a compound of the above types; as k decreases, c/k rises till it reaches a maximum value, after which it decreases again as for phthalic acid. For our solutions the mass-action law holds, if at all, over a very low range of concentrations indeed.

We then tested the applicability of the Kraus and Bray equation for electrolytes where the ionisation is low, i.e. $cA^2 = P(cA)^m$ or $k^2/c = Pk^m$, where P and m are constants.¹ From this equation we have $\log k^2/c = m \cdot \log k + \log P$. For hydrochloric acid in aniline and for aniline in acetic acid we found that the graph of $\log (k^2/c)$ against $\log k$ was roughly a straight line. But on working back from this line to values of k from given values of c , we found that the calculated values agreed only approximately with the observed values. For example, with aniline in acetic acid the constants were $m = 1.635$ and $P = 14.45$, and the average deviation of the calculated values of k from the observed values of k was -4% ; the Kraus and Bray equation was only an average equation over the range $c = 1.1$ to 0.2 . Similar results held for solutions of hydrochloric acid in aniline. Quite as good results may be obtained from a relation like $k = x(y - c)^n$, where x , y and n are constants; or, for example, for most of our solutions of hydrochloric acid in aniline by the equation $k = 538 c^2 - 4$, over the range of $c = 0.5$ to 0.1 . The plotting of complex functions, especially those involving logarithms, is liable to become quite misleading, if the errors introduced in obtaining those functions (and logarithms) are not allowed for.

The Kraus and Bray relationship reduces to $k^{2-m} = p \cdot c$, or $k = q \cdot c^p$, where q and p are constants, and thus $\log k = p \cdot \log c + \log q$. It is simpler to try the graph $\log k$ - $\log c$ than the graph of $\log (k^2/c)$ - $\log k$. For none of our solutions in this graph $\log k$ - $\log c$ a straight line over the whole range of the experiments, except perhaps for phthalic anhydride, for which substances however the results are not of the highest accuracy. For the aniline solutions of phthalic and salicylic acids and perhaps of acetic anhydride, the $\log k$ - $\log c$ graph is a straight line over a range of the lowest concentrations; over these concentrations therefore the Kraus-Bray modified equation holds. In general the $\log k$ - $\log c$ curves are concave to the $\log k$ axis, i.e. $\log k$ increases faster than $\log c$; for solutions of aniline in acetic acid the reverse holds.

It is clear that the relations between k and c for various electrolytic solutions are not covered by any simple extensions of the law of mass-action for any considerable ranges of concentrations. We may write provisionally that $k = q \cdot c^p$, where q is a constant and p is some function of c . If the form of the function p is the same for all electrolytes, then the constants there involved must alter greatly. For solutions of salts in water, $p < 1$, and the k/c curve approaches the zero asymptotically to the k -axis; and for many non-aqueous solutions $p > 1$, and the k/c curve approaches zero asymptotically to the c -axis. Even then one such equation can only hold for one electrolyte from zero to moderate concentrations, as a k/c curve usually exhibits a maximum at a certain value of c . The connection between k and c must indeed involve the reasons for ionisation and the relations between the ions and the solvent and the relations between the ions themselves.

¹ Kraus: loc. cit., p. 75.

² Kraus: loc. cit., p. 79.

Summary

Solutions in aniline are relatively poor conductors of electricity. The conducting solutions behave generally like typical non-aqueous electrolytic solutions.

Thus the specific conductivities rise so rapidly with increasing concentration of solute, that the molecular conductivities also rise rapidly with increasing concentrations.

No simple equation was found to express the relations between the specific conductivity, k , and the concentration of solute, c . Evidently $k \propto c^p$, where p , at least, is some function of c .

At very low concentrations some solutions in aniline behave like aqueous solutions and the molecular conductivity rises to a limit at zero concentration; more delicate experiments might extend the number of these solutions.

The stronger acids with aniline give solutions of which the conductivities tend to increase with the time. Assuming the initial conductivity is due to the formation of aniline salt, the subsequent formation of aniline and liberation of water will explain the increase of conductivity.

ON THE NATURE OF THE INFLUENCE OF HUMIDITY CHANGES UPON THE COMPOSITION OF BUILDING MATERIALS*

BY JAMES W. MCBAIN AND JOHN FERGUSON

Of all the fluctuating mechanical strains set up in building materials by varying influences, those due to fluctuating humidity are often five times greater than those due to the factor next in importance. The object of the present paper is to isolate this one factor and to investigate its precise nature.

To avoid misunderstanding it must be clearly stated that humidity change is only one factor in the decay of building materials. Hence when we proceed to point out as one of our definite results that certain building materials are wholly exempt from the operation of this factor, it is not to be forgotten that some of the stones may be especially liable to attack by other causes, such as chemical action of the sulphuric acid derived in surprising quantity from the air of towns.

Since there was no information extant as to the amount of water actually taken up by building stones under varying conditions of humidity, we have conducted a systematic series of measurements of the sorption of water vapour by typical materials, ranging from pure crystalline quartz to bricks, sandstones and limestones. It was then shown that parallel results are obtainable by the much quicker method of treatment with dyes such as methylene blue. Further insight into the phenomena involved is obtained by sorption experiments with vapours of organic solvents. The results are in accordance with the conception of micellar linkage which has been used in this laboratory in the explanation of the phenomena presented by jellies, soap solutions, detergent action and the viscosity of nitro cotton.¹ Hence we have suggested a highly tentative definition of a stone preservative.

Sorption of Water Vapour

Experimental Method.

The sorption balance of McBain and Bakr² was used. This consists essentially in suspending the substance to be investigated in the pan of a delicate spring balance made of fused silica fibre and observing the increase in weight when the substance is exposed to vapour (in this case water vapour) under varying conditions of temperature and pressure.

Fig. 1 shows a sorption tube set up ready for experiment. In use the upper portion of each tube is in an electrically heated air oven while the bottom part is in a water thermostat provided with a thermometer and stirrer, and a large number of tubes are set up side by side. The small portions of the tubes between the oven and the thermostat were heated by a wire coil.

*The work described was carried out for the Building Research Station of the Department of Scientific and Industrial Research and this note is communicated by permission of the department. Crown copyright reserved in Great Britain.

¹ See, for example, *J. Phys. Chem.*, **30**, 239 (1926).

² *J. Am. Chem. Soc.*, **48**, 690 (1926).

In Fig. 1 the silica spring S is suspended in the glass tube G from a hook projecting from the glass bulb B which is prevented from slipping down the tube by means of a slight constriction in the tube C'. A small bucket made of gold or platinum foil is suspended from a hook at the bottom of the spring. The bucket contains a small weighed quantity of the material under investigation (sandstone, limestone, cement, etc.). In the bottom of the tube, there is placed a small bulb W, almost completely full of water. The bulb is enclosed in a small test tube H, sealed off at the top, and having a small hole A blown in the bottom.

In setting up an experiment the bulb B, with the spring and the bucket suspended from it, is slipped down into the tube T until it rests on the constriction, the water bulb W having been previously placed in the bottom of the tube. The tube is then sealed off at the top K in the blow-pipe flame, and the narrow outlet tube X sealed to a high-vacuum air-pump. The tube is then evacuated until the interior pressure falls below 0.001 mm. During the evacuation the upper part of the tube containing the bucket is heated to 200° C by means of an electric oven, consisting of several turns of nichrome resistance wire wound on a wide glass tube, which slips over the sorption tube. When the pressure has fallen to the required value, the sorption tube is sealed off at a constriction in the narrow outlet tube X.

The tube is now supported in a vertical position, and the length of the spring read by means of a tele-microscope. The extension can be read by means of a vernier to 0.002 cm., corresponding usually to about 0.0001 gm.

The bottom of the tube containing the water bulb is now immersed in a freezing mixture of ice and water, or of carbon dioxide snow and ether. The water in the bulb freezes and in expanding breaks the bulb, so that water vapour is now admitted to the interior of the tube. It is necessary for this process that the water bulb be contained in the shielding test tube H, since particles of glass and ice are thrown violently about the interior of the tube when the bulb bursts, perhaps smashing the spring or capsizing the bucket.

The sorption tube is now supported vertically, with the upper part containing the bucket and spring in the electrically heated oven, and the lower part containing liquid water dipping into the thermostat at a lower temperature. The tubes are observed through a glass window, which is usually kept covered by insulating doors.

On the admission of water vapour to the interior of the evacuated tube by freezing the water bulb as just described, the substance in the bucket immediately begins to take up water from the vapour phase; since the spring has

FIG. 1

previously been calibrated, the increase of weight per unit extension length is known. Hence, by measuring the length of the spring, the amount of sorption is deducible to about 0.1 mg.

If the temperature of the upper thermostat is kept at a constant value, 50°C, while the temperature of the lower one is varied from 0° to 50°C, the behaviour of the material in the bucket can be investigated in atmospheres of differing degrees of humidity. The relative humidity is the ratio of the vapour pressures of water at the temperatures of the lower thermostat and of the bucket respectively.

By continuing this procedure at suitable temperatures, the relation between temperature and sorption at constant humidity may be studied, and also the relation between temperature and sorption at constant pressure.

The silica springs are made by coiling a long fibre of silica round a cylindrical carbon rod as described by McBain and Bakr (*loc. cit.*). The springs used extended about 1/10 mm. for an added load of one milligramme. In a few cases, springs three times as sensitive as this were used. Since an increase in length of the spring could be read with certainty to within 0.02 mm. an increase in weight of 1/15 of a milligram is detectable using the latter spring.

The maximum load which can be safely used on a spring of the first type is 0.5 gm. As the bucket weighs usually 0.1 gm., 0.4 gm of material is the maximum amount employed in these experiments. Usually not more than 0.3 gm. was used. Therefore with the ordinary type of spring, increases in the weight of the material could be read to 1/15% of the total weight.

Each spring was calibrated before use, by measuring its length under various loads. The calibration was carried out at several temperatures as the length of the spring, and the extension per unit length, decreases slightly with rising temperature, since the rigidity modulus of silica has a slight positive temperature coefficient. For this purpose a cylindrical glass oven, wound with several coils of nichrome is employed, inside which the spring is suspended. The oven is connected in series with a rheostat to the electric supply. The temperatures used were usually room temperature, 50°, 100° and 300°C.

Materials studied.

I. Miscellaneous siliceous materials.

- 1) Clear quartz crystal powdered.
- 2) Leighton Buzzard Sand.
- 3) Fibres of fused silica (average diameter = 0.004 cm.).
- 4) Kieselguhr (natural diatomaceous earth).
- 5) Filter cel ("treated" diatomaceous earth).
- 6) Gatton stone. This is a stone containing a very large amount (up to 40%) colloidal silica. It has been used as a building stone, but its use is now given up, owing to enormous disintegration on weathering.

Fe ₂ O ₃	2.08
Al ₂ O ₃	2.56
CaO	10.18 (17.7 CaCO ₃)
MgO	0.11
SO ₃	0.19
Alkalies (by difference)	4.48
	<hr/> 100.00
Crystalline silica	25.8%
Combined silica over	5.0%
Remainder (36%) colloidal silica.	

Most of the lime is present as carbonate, though a little CaSO₄ is present too. The aluminium and iron will be present as silicates.

II. Sandstones.

7) Millstone grit (Idle Quarry).

Analysis:—	%
Loss on ignition	2.24 (H ₂ O, CO ₂ & organic)
SiO ₂	85.79
Fe ₂ O ₃	1.68
Al ₂ O ₃	7.00
TiO ₂	0.24
CaO	0.52
MgO	0.22
SO ₃	0.48
P ₂ O ₅	0.05
K ₂ O, Na ₂ O	1.80
	<hr/> 100.02

Traces of Cl, Mn, SnO₂, BaO, F and free V₂O₅ were absent. The CO₂ and organic matter are very low and the composition is very close to that from Darley Dale, (vide infra), which consists of sand grains with orthoclase cemented with siliceous material. The same amounts of sulphates and carbonates occur as in the Darley Dale specimen.

Water absorption 2.5%

8) Millstone grit (Darley Dale). (Stancliffe Stone)

Traces of V₂O₅, SrO, BaO and F were absent. The stone consists of quartz grains with some orthoclase and a siliceous cementing material. Very small amounts of calcium phosphate and sulphate also magnesium and calcium carbonates are present.

Both these grits (7 & 8) are hard compact sandstones. They are fairly resistant to weather, but show movement, with changing moisture content.

Analysis:—	%
Loss on ignition	1.32 (H ₂ O, CO ₂ , organic)
SiO ₂	87.05
Fe ₂ O ₃	2.08
Al ₂ O ₃	5.85
TiO ₂	0.35
CaO ₂	0.32
MgO	0.24
SO ₃	0.54
P ₂ O ₅	0.04
Na ₂ O	0.78
K ₂ O	1.82
Cl	Trace
Mn	Trace
	<hr/> 100.39

Water absorption 6%

9) Kentish Rag.

A cretaceous limestone. The stone is fairly resistant to weather.

Analysis:—	%
Loss on ignition	29.20 (CO ₂ 27.2)
Total SiO ₂	32.15
Fe ₂ O ₃	1.80
Al ₂ O ₃	0.50
CaO	35.50
MgO	0.35
SO ₃	0.55
	<hr/> 100.05%

Water absorption 1.7%

The stone contains 61.8% CaCO₃, with CaSO₄.MgCO₃, and aluminium silicate etc. Most of the silica is present as crystalline silica, not more than 2% being combined.

10) Portland stone.

An oolitic limestone,

Analysis:—	%
Total silica	2.00
Crystalline silica	0.70
Water absorption 4.5%	

11) Monk's Park stone.

An oolitic limestone.

Total SiO ₂	0.36%
------------------------	-------

12) Dolomitic limestone (Gold Coast)

Composed chiefly of calcium and magnesium carbonates in molecular proportion.

Total SiO ₂	3.26%
Crystalline SiO ₂	1.21%
Water absorption	3.6 %

13) Chalk (Setch, Norfolk).

Total silica	3.82%
Crystalline silica	over 0.10%

This is a typical English chalk. They contain usually 90-95% CaCO_3 with varying amounts of SiO_2 , MgCO_3 , Fe_2O_3 and Al_2O_3 .

14) Stoneycombe stone.

This is almost entirely calcium carbonate similar to a marble.

Total SiO_2	0.46%
----------------------	-------

15) Buxton limestone.

One of the purest forms of limestone in the world, almost entirely CaCO_3 .

Total SiO_2	1.00%
Crystalline SiO_2	0.35%
Water absorption	2%

16) Sand-lime brick.

Analysis:—	%
Loss on ignition	6.04
SiO_2	82.62
Fe_2O_3	1.80
Al_2O_3	3.04
CaO	5.60
MgO	0.25
SO_3	0.21
Alkalies	0.60
	<hr/> 100.26
Combined silica	0.70%
CaSO_4	0.36%
CaCO_3	0.74%

Sand-lime bricks are made from slaked lime and sand, the pressure and moisture being supplied by superheated steam in containers. The proportions are about $7\frac{1}{2}$ parts quicklime to 100 parts of sand by weight, or one volume slaked lime powder to five volumes of sand.

17) Red rubber brick.

This is a soft brick intended to be cut or rubbed down. It is characterised by homogeneity of texture. The burning temperature is fairly high but not so high as, for example, blue Stafford brick.

18) Red wire-cut brick.

These bricks are made from clay in which iron is fairly plentiful say (5-8%).

19) Blue wire-cut brick.

Similar in composition etc. to blue Stafford (see no. 20.) The blue bricks appear to be peculiar to the Midlands as the clay must have a rather high iron content.

Water absorption	4%
------------------	----

20) Blue Stafford brick.

These, like the other blue bricks are a heavy compact form capable of standing high pressures. The water absorption is low, the bricks being

amongst those most impervious to water. The clay is normal in most ways, except for the high iron content, 8-10% usually, as the colour is due to the transformation of the oxide to the protoxide at the very high temperature to which they are burned. The period of burning is also longer than that with most others.

21) Fletton brick.

Fletton bricks are made from lower Oxford clay rich in deposits of marine and vegetable life. It is of the nature of a shale. The bricks are made under great pressure (120 tons per brick area) and are burned at about 1100°C.

Water absorption	20%
------------------	-----

22) Stock brick.

This type is a hard burned brick, usually containing blemishes. The clays used vary considerably, the bricks being produced in many localities.

Water absorption	20%
------------------	-----

23) Granite. (Meldon).

The sample used was a Dartmoor granite from Devonshire and the composition is usually richer in potash felspar than most granite. It is softer than many other types. Granites are essentially composed of quartz felspar and mica, the total silica,¹ being from 60% to 80%.

Sampling of materials.

The building materials were usually supplied in the form of small blocks or as small chunks. These were broken down into pieces about half an inch in diameter, and several of these were ground down in an agate mortar to a fairly fine powder. This was then thoroughly mixed and small portions, 0.2 to 0.3 gm. in weight, taken as the experimental material.

Numerical results.

All the measurements detailed in the following Table were carried out with the sample of material at a temperature of approximately 50° except where otherwise stated. Under the heading $x/m \times 1000$ is given the weight of water in milligrams, taken up from the vapour phase, by one gram of material. The results are in chronological order, and to save space the data in the first four columns are continued in the last four columns. In all cases at least one day elapsed between successive readings.

Sorption is very rapidly completed. It has often been observed, on setting the microscope on the bottom of the spring within one hour of adjusting the temperatures, and then leaving for 24 hours, that the spring point was still at the cross-wire intersection. True equilibrium was attained as is proven (neglecting Gatton stone and Kieselguhr which show hysteresis) by the agreement between values for increasing and decreasing humidity.

¹ The term crystalline silica in the analyses refers to compact uncombined crystalline forms and does not include any which is of a colloidal or absorbent nature which might also be present uncombined. The method adopted for estimating this crystalline silica depended on the far greater reactivity of silica liberated from combination and would include any free colloidal or "soluble" silica with the combined. As the silica in different silicates is liberated, with varying ease, a uniform method is difficult to devise and each case has been treated according to its known composition. The amounts of silicas as given are therefore only to be considered as tentative.

Experiments were carried out in independent duplicates only with Chalk, Dolomitic Limestone, and Millstone Grit, but further isolated points obtained with Millstone Grit and Sandstone fell upon the previous curves.

Discussion of Results obtained with Water Vapour

The results given in the preceeding tables are shown in graphical form. Figs. 2-4 embrace all the materials giving any sorption at all which did not show hysteresis.

Consideration of the graphs and the tables shows that the materials studied may be divided into three groups: (1) those which sorb practically no water at all or, where the small amount taken up remains constant over a wide humidity range; (2) those which sorb a small quantity, 1% or less, which varies somewhat with changing humidity; and (3) those which sorb a large amount of water (of the order of 10%) at high humidity and in which the amount sorbed varies greatly with the humidity conditions.

The first group includes pure quartz, pure limestones, and the bricks which have been burned or fired at a high temperature and also the granite studied. These materials take up practically nothing from saturated water vapour. All these materials are practically immune to humidity changes.

Moreover we can include in this group Portland stone and Monk's Park stone. These show no variation of the amount of water sorbed, over a wide

range of humidity, though a small amount of water is taken up on exposing them to water vapour. This is probably due to chemical combination with lime etc. In any case, the really important point is not the absolute amount of water sorbed, but the rate of variation of this amount with the humidity, as shown by the gradients of the curves expressing this relationship.

FIG. 2

1. Sandstone 50°C.
2. Millstone Grit 50°C.

Most of the bricks take up practically no water in an almost saturated atmosphere but we know from experience that when any of these bricks are immersed in water a relatively large amount of water is imbibed (red rubber 13%, Fletton 6-9%, Stock bricks 20%). The discrepancy is explained by the fact that the absorption from liquid water is not a case of adsorption by a colloid, but merely the filling up of the large or macroscopic pores in the brick. The water-immersion absorption figures merely measure the porosity of the material. The figures given in the table however give the amount of water taken into the colloidal constituents. *They are therefore measures of the amounts of colloid in the materials.* Bricks show no sorption and therefore have no colloidal constituents in this sense.

The second group includes ordinary building stone, such as the better sandstones which show only a small sorption. However, when this sorption is referred to the actual amounts of colloid material it becomes quite considerable. Thus the Idle Quarry sandstone examined sorbed only 1% of its total weight (at approximately saturation). It however consists of 88% of SiO_2 plus 12% CaO , MgO , Fe_2O_3 . Most of the silica is present as quartz crystals, the remainder being combined with the metallic oxides to form binding material. If we assess this colloidal binding material as 10% of the weight of the stone, we see that this binding material, which alone is reactive,

sorbs 10% of its weight in a saturated atmosphere—and is therefore quite comparable with the substances in group 3. The artificial sand-lime brick must also be included in the second group.

The materials in the third group consist largely of amorphous silica as for example Kieselguhr, Filter Cel, Gatton stone. It is important to remember

FIG. 3

1. Portland Stone at 50°C.
2. Monk's Park Stone at 50°C.
3. Dolomite Limestone at 20°C.
4. Chalk at 50°C.
5. Kentish Rag at 50°C.

that in contrast to these the crystalline silica, quartz, sorbs practically no water even in an almost saturated atmosphere; for it proves that the sorption exhibited by sandstone, and hence all the trouble due to swelling, is due to the amorphous binding material in the sandstone.

Microscopic examination of sandstones indicates that they are composed of small grains of quartz embedded in an amorphous cementing material, which in some cases may consist of calcium or magnesium silicates and in others may be calcium or magnesium carbonates.

This cementing substance resembles a gel. For example, as will be shown, it can be stained with dyes, and it sorbs water vapour in amounts varying continuously with the vapour pressure. On imbibing water, the sandstone increases distinctly in volume, paralleling the behaviour of organic gels.

In ordinary building stones, what colloidal gels exist, are present in small amount. But in the case of calcareous hydraulic cements such as Portland cement, it is now generally believed that the set cement consists mainly of gels of calcium silicate, and perhaps of calcium aluminate, hardened by desiccation. This view was first advanced by Michaelis¹ and has received considerable support, especially as a result of the researches of the U. S. Bureau of Standards.²

¹ Chem. Ztg., 17, 892 (1893).

² A. A. Klein and A. J. Phillips: U. S. Bur. Standards, Technological Paper 43 (1914); P. H. Bates and A. A. Klein: 78 (1916).

Even in the case of an ordinary lime mortar, and in plaster of Paris, it seems that the tenacity of the material is due to the presence of a gel.

Desiccated colloidal substances such as glue possess high tensile strength which we should ascribe to linking of the micelles by dehydration. That a structure with irregularly oriented units such as we assume an amorphous

FIG. 4

- | | |
|--------------------------|---------------------------------------|
| 1. Leighton Buzzard Sand | 3. Stock Brick |
| 2. Fibres of Silica | 4. Sand-lime Brick (unheated) at 50°C |

substance to be, should possess a high tensile strength compared with a crystal, is easily understood when we consider the existence of cleavage planes, glide planes etc. in the latter.¹

As all gels shrink on drying and expand on absorption of water, considerable movements may result in cement from this cause. Moreover, the hydration processes with production of gel continue slowly in the interior of a cement long after the mass has set. In addition slow dehydration of the gels already present goes on. Thus a series of complicated volume changes occur causing internal stresses.

Any method for the prevention of this slow periodical hydration and dehydration in the case of certain stones and cement must be based primarily on an intimate knowledge of the colloidal structure of the materials used.

From the results with pure limestones it may be suggested that the cohering of such limestones is not due to the presence of an inter-grain colloidal cement, and probably not to the interlocking of crystals of calcium carbonate, but rather to their true adhesion according to the hypothesis of McBain and Lee.

¹ McBain and Lee: Proc. Roy. Soc., 113, A, 606 (1927).

Hysteresis observed with Kieselguhr, Filter Cel and Gatton Stone

Figure 5 illustrates for Gatton stone the hysteresis that was observed with three materials; namely, Gatton stone, Filter Cel and Kieselguhr, all containing large amounts of colloidal silica. The phenomenon is well known from the classical studies of van Bemmelen on silicic acid allowed to set without stirring. Apart from the obvious proof of the existence of colloidal materials

FIG. 5

in this type of (unsatisfactory) building material, the data are of great interest in showing the permanent change that is occasioned in such stone by its first dehydration after removing from a wet quarry. A process that is only completed by subsequent cycles of humidity change, such as are illustrated in the single recorded experiment.

Zsigmondy was the first to explain such curves on the basis of the micellar theory on the assumption that the material is a loose aggregate of ultra-microscopic colloidal particles or micelles. The surface of each micelle is shown to be capable of true adsorption, perhaps only one molecule deep, but the relatively large caverns and interstices so coated form pores playing the role of capillary tubes in which liquids may condense in bulk. According to our extension of the micellar theory the colloidal particles are linked together at the points of contact and this coupling may be effected by dehydration.

There are two current explanations of the hysteresis observed when emptying and filling the pores respectively. In the first explanation the emptying is assumed to be due to evaporation from the curved liquid surface, whereas when filling the wetting is less complete, the contact angle if any is greater and therefore the vapour pressure for a given amount is higher. According to this suggestion the hysteresis should be largely confined to the steepest portions of the curve (for Kieselguhr and Filter Cel between the

relative humidities of 0.27 and 0.4); whereas, in all our cases hysteresis¹ is observable throughout. According to the second explanation the hysteresis is ascribed to air entering the emptied pores and interfering with their wetting and filling, and Patrick has shown that thorough evacuation can largely eliminate such hysteresis.

FIG. 6

This however is not the case with the materials here studied. A sample of Filter Cel was specially prepared for measurement by employing a vacuum of 0.00001 mm. and four times in succession pure water vapour was introduced, allowed to condense upon the Filter Cel and again completely removed by evacuation at 200°C. Thereupon the experiments recorded in the table were carried out with the results shown in Fig. 6 where hysteresis is still observed. The curves are however no longer of the form familiar through the work of van Bemmelen and his successors such as Zsigmondy, Anderson and Patrick. We therefore seek a third explanation of this portion or type of the hysteresis and we find it in the micellar theory already mentioned.¹

The actual swelling of these "rigid" gels has been measured at the Building Research Station and it has even been shown there by F. T. Meehan that charcoal in adsorbing a gas such as carbon dioxide likewise swells appreciably. This we would attribute to an uncoupling of certain linked particles through double decomposition; that is, through addition of a molecule of water to each valency bond thus broken and exposed. Incidentally, this uncoupling through satisfaction of the valencies with mutually independent molecules of water should not only loosen but weaken the structure. On the whole, much of the coupling should tend to be irreversible, the stone should shrink and become stronger and less susceptible to moisture change. For example, sorption of nitrocellulose may be reduced to two thirds of its original value by this means.

¹ See, for example, McBain: *J. Phys. Chem.*, **30**, 239 (1926).

Finally, for interest it may be noted that the largest pores in Filter Cel and Kieselguhr are about 9 Ångstrom units in diameter and that condensation of water at relative humidities of 0.3 and 0.4 would take place in capillaries of 7.7 and 10.1 Ångstrom units in diameter respectively.

Sorption of Dyes by Building Materials

The staining of minerals by dyes has been used as a criterion of their colloidal nature.¹ This method has limitations. A few crystalline minerals, owing to their enormous basal surfaces notably, mica and kaolinite, also take up dyestuffs. Moreover the amount of dye adsorbed depends on the degree of dispersion of the material. Dyes are also used for estimating the colloid content of soils.²

It is interesting to find that a parallelism exists between the sorptive capacity of the building materials for water, and their absorption of dyes. For this purpose two dyes were employed; viz. methylene blue, and magenta. Dilute solutions of methylene blue, mixed with dilute solutions of either hydrochloric acid, caustic soda, or calcium hydroxide, underwent no change in shade, compared with a blank consisting of dye solution mixed with distilled water, and made up to the same value as the acid and alkali mixtures. The magenta solutions on the other hand were precipitated by lime water, the colour base separating. Hence, before treatment with the magenta solution, lime had to be removed from the building stones by means of ammonium oxalate.

In the case of methylene blue, quantities of one gram of fairly well powdered samples of the stones, were each shaken thoroughly in stoppered test tubes with 10 cc of an aqueous solution of 1 gram of methylene blue in 5 litres, and then allowed to settle, when the shade of the supernatant liquid was observable. With magenta, the samples were first treated with 15 cc. of saturated ammonium oxalate solution, and well shaken.

After standing 24 hours, the tubes were centrifuged, and the supernatant solution poured off. Distilled water was then added and centrifuging repeated. This was done six times. After being thus washed free from ammonium oxalate, 10 cc of the magenta solution (1 gram dye per 5 litres of distilled water) were added, and the tubes shaken up and allowed to settle.

From Table II it is seen that the order of increasing dye stuff absorption is practically the same for each dye.

The order of colloidity as determined by the staining methods is apparently in agreement with that deduced from sorption experiments with water vapour. Thus the bricks and quartz take up practically no dye, in agreement with the sorption experiments indicating their non-colloidal nature. The non-colloidal nature of the limestone is also well shown by the zero or negligible dye absorption, while the definitely colloidal sandstones react markedly.

¹ Dittler: *Kolloid-Z.*, 4, 277; 5, 93; Endell: 244 (1909).

² U. S. Dept. Agriculture, Prof. Paper, Bull. 1193 (1924).

The only notable disagreement between the two methods is shown by granite. This is probably due to the presence of the mica in the granite, since, as already mentioned, mica adsorbs dye.

TABLE II

Methylene blue		Magenta	
Substance	Shade of supernatant liquid	Substance	Shade of supernatant liquid
1. Red wire-cut brick.		1. Red wire-cut brick.	
2. Red rubber brick.		2. Stock brick	Indistinguishable from blank.
3. Stock brick.	Indistinguishable from blank.	3. Red rubber brick.	
4. Quartz powder.		4. Stoneycombe stone.	Very slight lightening of shade in direction 3 to 7.
5. Stoneycombe stone.		5. Buxton limestone.	
6. Buxton lime-stone.		6. Dolomitic limestone.	
7. Dolomitic limestone.	Exceedingly slight lightening of shade.	7. Portland stone.	Almost indistinguishable from blank
8. Portland stone.	Rather lighter than above.	8. Granite.	Slight lightening in shade.
9. Granite.	Considerably lighter than blank.		
10. Kentish Rag.	Liquid only tinged	9. Sand-lime brick.	
11. Sand-lime brick.	colour. Depth of shade decreasing	10. Chalk.	
12. Chalk	from 10 to 12.	11. Kentish Rag.	
13. Millstone grit.	Colour completely removed.	12. Millstone	Colour almost completely abstracted.
14. Sandstone.		13. Sandstone.	
15. Gatton stone.		14. Gatton stone.	Absolutely colourless.

The order of decreasing intensity of shade was observed within an hour of adding the dye-stuff. On keeping the solutions in contact with the materials, it was observed that the order and colour intensity remained unchanged, even after three months, in the case of methylene blue. The magenta solutions faded however in some cases after 24 hours. This applied to the carbonates (Portland stone, Stoneycombe stone, Buxton and Dolomitic limestones). This fading was probably due to the formation of free lime in solution. Hence methylene blue is a much more satisfactory reagent than magenta for this purpose.

Effect of Heat on Colloidal Structure

The application of colloid chemistry to mineralogy and petrology is a development of the present century. Such studies originated with Cornu¹ and his co-workers, but little has been done except in developing methods for the recognition and classification of colloid minerals. The literature is very scattered, but two extensive summaries have appeared, one by Marc and Himmelbauer² and the second by Scott.³

The non-colloidal character of burned bricks has already been noted. This is a significant observation. They are prepared from a colloidal substance—clay—and hence it must be concluded that the high temperature to which they are subjected during manufacture effectively destroys the colloid present. This is in accord with the observation of Bouyoucos⁴ that soils (and also silica gel) on heating to 800°C, lose their colloid character, as manifested by dye sorption, heat of wetting, and plasticity.

To confirm this, samples of powdered sandstone placed in a platinum capsule were heated in a silica tube in a small oven for three hours to temperatures of 500°C, 680°C and 800°C respectively. Small quantities of the heated samples were then employed in water sorption experiments. The results were as follows:

	Relative humidity	$x/m \times 1000$
1. Sandstone heated to 900°	0.89	0.0
2. Sandstone heated to 680°	0.60	1.0
	0.73	2.0
	0.99	6.0
3. Sandstone heated to 500°	0.54	6.1
	0.99	11.0

Thus after being heated to 900° sandstone sorbs no water vapour even in an almost saturated atmosphere, showing that the colloidal structure has been completely destroyed by heating.

After heating to 680° the power of sorbing water has been diminished, but heating to 500° apparently does not alter the colloidal structure markedly, since the sorption exhibited at the humidities given is comparable with that of untreated stone.

The absorption of methylene blue by sandstone and Gatton stone heated to several different temperatures was also determined:

¹ F. Cornu: *Kolloid-Z.*, 4, 15 (1909).

² R. Marc and A. Himmelbauer: *Fortschritte Min. Kryst. Petr.*, 3, 33 (1913).

³ A. Scott: "Fourth Report on Colloid Chemistry," 204 (1922), now under revision.

⁴ Bouyoucos: *Soil Science*, 17, 135 (1924).

	Sandstone
Temperature	Colour of dye solution
960°C	Indistinguishable from blank.
940	Very slight lightening in shade.
850	Solution colourless.
750	Solution colourless.
	Gatton Stone
950	Indistinguishable from blank.
850	Slight lightening in shade.
750	Solution colourless.

Again as shown by dye absorption, the effect of heating to 900°C is to destroy the colloidal matter present. The suspension settled slowly until the material had been heated to 900°C.

× descending 50°C

Sorption of Various Liquids by the Intergrain Cement present in Sandstone

Colloids are characterised by dehydration curves free from any sharp discontinuity but this characteristic is shared by the incompletely studied group of minerals related to the zeolites. A good deal should be deducible from the study of the exact shape of these sorption curves, and the type to which they belong.

FIG. 8

● 18°C.

○ ascending 50°C

× descending 50°C.

Weigel¹ has shown that the zeolite chabasite absorbs large amounts of the vapours of ethyl and methyl alcohols and formic acid, but takes up practically no acetone, ether, or benzene. McBain² has pointed out that this can be

¹ Z. Krist., 61, 135 (1924).

² Kolloid-Z., 40, 1 (1926).

explained on the assumption that the interstices in the zeolite crystal lattice are too small to admit the larger molecules of the latter liquids, and on this basis has calculated the size of the openings to be less than five Ångström units. This therefore presents one distinctive type.

The active material or cement in the sandstone might conceivably consist of hydrated crystals of the zeolite type, or it might be a gel consisting of an agglomeration of ultramicroscopic crystals, or a gel in which the units are noncrystalline, or lastly, a glass. This should be determinable if the active material could be isolated and its sorption carefully studied with various liquids. Determination of the nature and structure of this cement should lead to methods for the destruction or the inactivation of the cement, preferably without destroying its cementing properties. Preliminary measurements of sorption have been carried out with two samples in which the colloidal material in sandstone has been concentrated by elutriation.

For this purpose, some pieces of sandstone were ground somewhat finely in an agate mortar, and the powder placed in a flask containing distilled water, which was then shaken violently. The mixture was then allowed to settle for half a minute (which was quite sufficient for the fairly larger compact grains of quartz to settle out), and the supernatant liquid poured off and filtered. The contents of the filter paper were then dried in the steam bath. The specimens thus obtained were of a pronounced yellow shade.

Results of the sorption experiments are presented in Tables III and IV and in Figs. 7 and 8. It should be pointed out at once that the elutriation has effected at least a partial concentration of the colloidal matter since the sorption is about doubled. Further, the curves, particularly with specimen 1, exhibit a distinct S-shape similar to that of certain gels.

				50.0	3	0.07	2.7

The amounts of various liquids taken up by the second specimen of inter-grain cement are tabulated for comparison for two values of relative humidity, 0.3 and 0.8, in Table V.

TABLE V

Liquid	Humidity	Amount ($\times 100$) taken up by 1 gm.		Humidity	Amount ($\times 100$) taken up by 1 gm.	
		Vol.	Weight		Vol.	Weight
Water	0.8	2.0	2.1	0.3	1.0	1.0
Benzene		0.95	0.85		0.6	0.7
Methyl Alcohol		1.9	1.6		1.2	1.0
Ethyl alcohol		1.26	1.0		0.5	0.4
Chloroform		1.0	1.5		0.75	1.1
C_8H_{18}		1.2	0.8		0.45	0.35

It is seen that though there are variations from liquid to liquid all the substances are sorbed independently of whether the molecules are large or small. Certainly the substances with large molecules (benzene, octane) are not sorbed in such large amounts by weight as those with small molecules (water, methyl alcohol) but there is no complete blotting out as in the case of chabasite. The evidence points towards a gel or micellar structure rather than a skeleton space lattice such as is exhibited by dehydrated zeolites or certain catalytic

oxides or probably certain carbons. This is not surprising, because of the sedimentary origin of sandstone. Water and chloroform are sorbed most and each to about the same extent. Possibly if accurate readings could be taken at humidities close to saturation the weights of the several liquids taken up would be more nearly in ratio of their densities. When sandstone is immersed in any one of these liquids, the weight taken up is proportional to the density of the liquid.

Heats of Sorption by Building Material

The heats of sorption are calculable by means of the Clapeyron-Clausius equation wherever we have values for the pressure corresponding to the same amount of sorption at any two temperatures. When the isotherms at various temperatures plotted against relative humidities are independent of the temperature, the heat of sorption is equal to the heat of condensation of the pure liquid. When the heat of sorption is greater the values for x/m are less at higher temperatures. The differential heats of sorption at temperatures between room temperature and 50° C. have been calculated for typical values of relative humidity, and the results are collected in Tables VI and VII, for building materials and Specimen II of intergranular cement of sandstone respectively. The heats involved are only a little greater than the heats of condensation of the vapour to pure liquid, given in the table for comparison. The heats are greater at low humidities.

¹ From Table VII.

Stone Preservatives

Many substances and materials have been proposed as stone preservatives but it would seem clear that different types of stone would require different types of preservative and that different types of preservative are necessary to counteract different attacking and disrupting agencies. Pure limestone for example needs no preservative against fluctuation of humidity but rather against chemical attack.

Confining ourselves to the discussion of a preservative against effect of changes in humidity of materials such as sandstone, we proceed from the conception at which we have arrived for the mechanism of the swelling process. In the original structure the micelles of the intergranular gel are stuck to each other by residual valencies. When water vapour is sorbed its molecules have a superior attraction for the micelle valencies. They disrupt some of the valency bonds and appropriate the broken bonds. The action is the same as the loosening of a glass stopper by the penetration of an oil film which separates the two glass surfaces by uniting with each of them (McBain: loc cit).

It follows that if the free and disruptible valencies in the gel can be satisfied permanently with some substance, swelling is eliminated. To prevent the swelling, all that is necessary is to satisfy the valencies of the micelles permanently with a substance of higher chemical affinity for them than water. Water would then not be taken up except by capillarity (harmless except in frost) and even then not if the capillary interspaces were completely blocked up.

This then is a tentative definition of a stone preservative against moisture movements. A stone preservative is a substance which in presence of water is preferentially sorbed by the mineral gel, remaining in combination permanently.

Summary

1. A systematic study has been made of the sorption by typical building materials at various degrees of humidity both of water vapour and of other liquids.
2. Certain building stones are shown to be exempt from disintegrating action due to this particular cause, fluctuating humidity.
3. It is shown that the intergrain cement of such stones as sandstone is colloidal whether siliceous or amorphous zeolitic, and an explanation is given of the moisture changes and swelling observed, upon the basis of the micellar hypothesis leading to a suggested definition of a stone preservative against this particular type of disintegration.
4. Parallel results are obtained by staining with dyes.
5. After being heated to 850° sandstone loses its power of sorbing water vapour or dyes.
6. The heat of sorption equals heat of liquefaction in the case of vapour of octane, but is greater in the case of polar liquids.

A GAGE FOR THE MEASUREMENT OF HIGH VACUA

BY ROBERT E. BURK*

Modern developments in high vacuum technique have made the rapid production of vacua of the order of 10^{-7} mm. of mercury a relatively simple matter, and have given both physicists and chemists powerful experimental methods of attack. However, in applying the new high vacuum technique to chemical problems, there are demands which perhaps come up more frequently than in work in physics; e. g. the chemist can seldom dispense with stop-cocks to advantage, he often works with compounds which are decomposed by hot metals, electronic bombardment, etc., and in many of his problems he must evacuate a vessel at frequent intervals.

The standard instrument for the measurement of high vacua is the McLeod gage, but it is not considered practicable below 1×10^{-5} mm. of mercury. For measuring pressures lower than this,¹ the Knudsen gage, the Dushman ionization gage, and the molecular gage have been used. The Knudsen and molecular gages are fragile and difficult to construct. The ionization gage cannot be used in chemically sensitive systems.

The McLeod gage has been extended by Pfund² by combining its principle with that of Pirani's hot wire gage. A McLeod gage with electrodes in the capillary, (serving as a rough guide to the pressure of the gas compressed into the capillary), has been used by Klayfeld,³ and by the writer.⁴ Neither of these can be used for measuring the pressure of chemically sensitive gases, and also have other disadvantages.

Description of the New Gage

A gage, shown in Fig. 1, has been constructed which combines the principles of the McLeod gage and the quartz fibre manometer. It can be used with any gas, or any vapor whose vapor pressure is large compared with that of mercury. The gage is easily constructed, and simple in operation. It has no metal parts, can be baked out, and can be calibrated *in situ* without a previous knowledge of its dimensions.

The gage was constructed of Pyrex glass. The volume of V (Fig. 1) was about 330 cc., that of the chamber F, containing the quartz fibres, was somewhat less than 10 c.c. The gas in V was therefore compressed more than thirty times when the mercury was raised from the cut off C to the level L. Two quartz fibres, joined together at the bottom, were used, as suggested by

Coolidge.¹ This eliminates the complex motions which are sometimes set up in the single fibre, and by trial was found to be well worth while. The fibres were 5.5 cm. in length and 0.068 mm. in diameter.

The fibre chamber *F* communicated with *V* by means of a stout tube *t* (the bore should not be too small), to which was sealed a glass cup *A*. The cup was insulated with felt. Mercury vapor and other vapors were condensed in *t* by placing a suitable cooling agent in *A*. The temperature should be

properly chosen so that the vapor can be frozen out to a negligible pressure, or, in case the vapor registers on the instrument with which the gage is compared for purposes of calibration, so that it can be considered as a fixed gas. In this work liquid air and CO₂-ether snow were used. The latter is recommended since at liquid air temperatures the adsorption processes are greatly magnified, and also the vapor pressure of CO₂ falls within the range of usefulness of the gage.²

Due consideration must be given to the processes in the cooled tube *t* in order to avoid erratic readings. Thus if *A* is kept at the temperature of ether-CO₂ snow for a continued period when the fibre is used for measuring pressures greater than the vapor pressure of water at that temperature, traces of ice will collect in the tube. If one then attempts to use the manometer for pressures less than the vapor pressure of ice at the

FIG. 1

temperature of ether-CO₂ snow, water vapor will contribute to the recorded pressures due to the rather slow evaporation of ice at that temperature. Consistent results over the entire range reported were obtained only when the air admitted to the system was that which had stood in a large vacuum bottle, containing 500 grams of phosphorus pentoxide, which was used to back the mercury condensation pump.

The bulb *V* was connected with a larger bulb *V*₁, as in the Gaede form of McLeod gage. *V*₁ was filled with mercury which was heated in vacuo. The tube through which the mercury was introduced was then sealed off with the pump running. *V*₁ was raised and lowered between two fixed points by means of a mechanical device. (Weights, working over the pulleys *P* balanced the weight of the mercury). This rendered the operation of the gage very easy. The connection between *V* and *V*₁ was made with enamelled rubber tubing, which was evacuated before introducing the mercury. This tubing was sur-

¹ Coolidge: *J. Am. Chem. Soc.*, **45**, 1637 (1923).

² Dushman: "Production and Measurement of High Vacuum", 78 (1922).

rounded by larger tubing, and the space between was kept evacuated. For extending the range of the gage, the connection between V and V₁ should be all glass, e. g. a universal joint made from three slip joints. This would minimize evolution of gas from the mercury, which was believed to be a source of error at the highest vacua in this work.

Table I gives the results of the calibration of the gage against a McLeod gage, and the calculation of unknown pressures by its use.

TABLE I

Ave. half life of fibre (sec's)	Recip. of half life $\times 10^3$	Position of mercury	P McLeod mm. $\times 10^4$	P calculated mm. $\times 10^6$
unsteady		lowered	Bubble invis.	(1.5 \pm 0.3)
385	2.6	raised		60.0 \pm 10
465	2.15	lowered	small bubble	(21.0 \pm 1.0)
131	7.63	raised		810 \pm 20
385	2.6	lowered	60 \pm 10	
60	16.67	raised		2350 \pm 20
321	3.12	lowered	90 \pm 10	
37	27.0	raised		3900 \pm 20
225	4.4	lowered	240 \pm 30	
18	55.5	raised		8150 \pm 20
184	5.43	lowered	510 \pm 30	
89	11.23	lowered	1250 \pm 100	
33	30.3	lowered	4500 \pm 100	

The values of P (calculated) were obtained by interpolation, using the straight line obtained by plotting the values of P (McLeod) against reciprocal half life of the fibre. The values of P (calculated) in brackets were obtained by dividing the corresponding pressure with the mercury raised by 38.8, the ratio of the volumes of the bulb V to the chamber F. This ratio of volumes is obtained, within the limit of experimental error, when the pressure with mercury raised is divided by the pressure with the mercury lowered in the other cases.

When traces of water vapor were present, the data in Table II were obtained. The vapor pressure of ice at $-76.8^\circ\text{C}.$ is added to the McLeod readings.

TABLE II

Ave. half life of fibre (sec's)	Recip. of half life $\times 10^3$	P (McLeod) mm. $\times 10^6 + 0.00075$
129	7.5	950
106	9.43	1150
92	10.86	1600
77	12.98	1950
49	20.40	2630
45	22.20	2950
28	35.70	5450
20	50.00	6750
16.5	60.55	8850

The mercury was lowered in each case, and the McLeod readings are subject to variations similar to those mentioned in the previous table.

The quartz fibre manometer was originally studied by Haber and Kerschbaum,¹ who give the following equation for the relation between the pressure, p , and the time, t , for the amplitude of the vibration to decrease by half

$$b = (\Sigma [p M^{1/2}] + a)t$$

a and b are constants. $\Sigma [p M^{1/2}]$ represents the sum of the products partial pressure \times (molecular weight)^{1/2} for all the gases present.

With the bifilar manometer used in the present experiments, a straight line was obtained when p was plotted against $1/t$, over the pressure range 6×10^{-5} mm. of mercury to 8.85×10^{-3} mm. of mercury, as predicted by the above equation.

The readings of the new gage were somewhat variable at the highest vacua, and in such a direction as to indicate slight adsorption on the walls of the vessel, and occasional liberation of gas, presumably from the mercury. The gage could be improved by making the connection between V and V_1 all glass, as previously mentioned, and by placing V and F in thermostats. The ratio of the volume of V to that of F could easily be increased to 300. The range of the instrument could thus be extended to 1×10^{-7} mm. of mercury without inconvenience.

The instrument can be used as an ordinary McLeod gage from $p = 0.00885$ mm. of mercury, (where the half life of the quartz fibre becomes small), to the range of the ordinary manometer. The side tube t , for equalizing capillary depression, and the scale S would then be used, as in the usual McLeod gage.

By measuring the difference in level between the mercury in V_1 and in the tube T , using the scale S_1 , or a cathetometer, the gage can be used for measuring pressures up to atmospheric. A single set up of this type may thus be employed for measuring pressures over the range atmospheric pressure to 1×10^{-7} mms. of mercury.

Description of Stopcocks employed

Connections to the mercury pump etc. were made through two way stopcocks of the type shown in Fig. 2, which can be used either with a lubricant, or mercury sealed with no lubricant. The bore in these stopcocks was 14 mm. in diameter \times 2 mm. in length. The enormous saving in time of evacuation resulting from the use of such stopcocks is apparent when its dimensions are substituted in Dushman's formula.²

$$Q = \frac{p_2 - p_1}{\left[\frac{2.394 L}{d^3} + \frac{3.184}{d^2} \right] \sqrt{\frac{M}{83.15 \times 10^6 T}}}$$

¹ Haber and Kerschbaum: *Z. Elektrochemie*, **20**, 296 (1914).

² Dushman: *Int. Critical Tables*, **1**, 91 (1926).

Let $p_2 - p_1 = 0.01$, and $T = 295$; then Q , the amount of gas flowing through the bore in cc. per sec is 125 when the above dimensions of the large bore stop cocks are substituted, and 0.714 when the dimensions of ordinary mercury seal stop cocks are substituted e.g. 2 mm. bore, 17 mm. long. The value 0.714 would again be very much reduced by clogging with grease, which is so difficult to avoid with small-bore stopcocks.

FIG. 2

Summary

A gage combining the principles of the ordinary manometer, the McLeod gage, and the quartz fibre manometer has been described, which is capable of measuring pressures from several decimeters of mercury to 1×10^{-7} mm. of mercury. It has been tested for pressures down to 1×10^{-6} mm. of mercury.

A two-way stopcock has been described which has been found to be very useful in working with high vacua.

The writer wishes to express his best thanks to the National Research Council for a Research Fellowship, and to Cornell University for apparatus and laboratory facilities.

THE BASIC VISCOSITY OF ICE-CREAM MIXES

BY ALAN LEIGHTON AND OWEN E. WILLIAMS*

The purpose of this paper is to demonstrate that there exists in normal ice-cream mixes a measurable basic viscosity, that is, a viscosity independent of changes in mechanical structure which take place when the mix is allowed to stand. This paper also shows that the change in value of this basic viscosity with variation in water concentration, at constant temperature, follows closely a modified form of the equation given by Arrhenius,¹ $\log \eta = \Theta c$.

When freshly prepared ice-cream mixes are allowed to stand at low temperatures they show a marked increase in viscosity. In commercial practice freshly prepared mixes are held for a period of at least twenty-four hours before being frozen, as it is the common belief that this increased viscosity is desirable. This procedure is known technically as ripening, and is sometimes called 'aging.'

A study of the viscosity of such a ripened mix shows that any mechanical agitation reduces the viscosity, and also that, with successive passages of the mix through a viscometer of the Ostwald type, the time required for the passage of the liquid gradually decreases to a value dependent upon the instrument itself. These phenomena are aptly described in an abstract² of a paper by Weissenberger³ dealing with the structure of disperse systems. Portions of this abstract are quoted:

"Dispersoids, more particularly emulsoids, whose concentration exceeds a certain limit, tend to form uniform secondary aggregates of the primary particles of the disperse phase, probably as the result of a special hindering of the free movements of the particles. The primary particles, which are ultra-microscopic aggregates of molecules, are very stable and reproducible. . . . In turn, secondary structures may unite to form aggregates of still higher orders. . . . These structures of higher orders are easily broken down, for example, by mechanical agitation, by shaking, or by forcing the solution through capillaries. If the viscosity of such an emulsion is measured in an Ostwald viscometer, it is bound to fall off with successive passages through the capillary until a constant value is obtained, the magnitude of which depends upon the size of the capillary. If the dispersoid is then allowed to rest, the viscosity slowly increases again as the structures of higher order are again formed."

From the foregoing it is apparent that as soon as ripened ice-cream mix enters the freezer the dashers will reduce the existing viscosity. If the in-

² Chem. Abs., 15, 3777 (1921).

³ Kolloid-Z., 29, 113-24 (1921).

creased viscosity of this ripened mix is due to the development of a mechanical structure, when this structure is broken down the viscosity obtained should be a basic value, independent, within certain limits, of the rate of stirring.

For clearness, this paper will refer to the viscosity of the unagitated ripened mix as the *apparent viscosity* and to that obtained upon agitation as the *basic viscosity*. The existence of this basic value was demonstrated as follows:

An unflavored ice-cream mix was made up, as is customary, from unsweetened evaporated milk, cream, cane sugar, and water, with the addition of a small amount of gelatin. This mix was pasteurized at 63°C., for one-half hour, homogenized at a pressure of 2500 pounds per square inch while still hot, immediately cooled, and stored for a day at a temperature of about 2°C. The total solids content of this mix was 36.3 per cent. Its viscosity when freshly prepared (measured at 0° C.) was found to be 9.11 centipoises (cp). The next day the apparent viscosity was > 50 cp. A portion of the mix was then run into a horizontal-type, brine-cooled freezer of six gallons capacity. The freezer was filled completely so that air could not be whipped into the mix by the dasher. When the mass was brought to a temperature of 0°C., the dashers were started at a speed of 130 R. P. M., the normal speed of the freezer. At intervals of five minutes for a period of one hour samples were drawn from the freezer into small flasks, packed with snow, and carried to the viscometer, which was immersed in a constant temperature bath held at 0°C. The viscosity value was found to be constant for this period of time at 36.31 cp. The basic viscosity was therefore reached quickly in the freezer. To check this value, portions of the same mix were placed in small side-necked filter flasks, the flasks evacuated of air at the pump and then shaken on a shaking machine of two-inch stroke at a rate of about 275 strokes per minute for various periods up to one hour, care being taken to prevent the mix warming appreciably. The same constant basic viscosity value was obtained as in the freezer. As a third check, about 400 cubic-centimeter portions of the mix were placed in 600 cubic-centimeter beakers, set in snow, and stirred rapidly with a small laboratory stirrer. The basic viscosity of these samples remained constant up to periods of one hour at the same value given by the other experiments. These results have been repeatedly obtained, although it has been found that the structural viscosity of more concentrated mixes could not be completely broken up by the shaking machine or the stirrer.

Now Arrhenius, has shown for colloidal solutions:

$$\log \eta = \Theta c$$

where η is the viscosity (in centipoises), c the concentration (molecular concentration, or with substances of high molecular weight, parts per 100 of solvents), and Θ a constant. This equation is that of a straight line passing through the origin. In other words, if the concentration of the solution under investigation becomes zero, the logarithm of viscosity is zero, or the viscosity value of the solvent is one, that of water at 20° C. The experiments herein described were carried out at 0°C where the viscosity of water is 1.796. It seems best therefore to express the equation as

$$\log \eta = \Theta c + k.$$

where k is a constant and, theoretically, should equal $\log 1.796$ or $.2544$.

As further proof that there is a true fundamental viscosity, measurements were made of the basic viscosity of ice-cream mixes of varying water content. Since it can be shown¹ that probably not more than half the water of an ice-cream mix is ever changed to ice in the freezer, the limiting concentration was that of a two-to-one mixture. Three mixes of different relative fat, milk solids and sugar contents were chosen, as shown in Table I. In the case of mix No. 1 four separate portions, of the different water concentrations in-

FIG. 1

Logarithmic plotting of basic viscosity against direct plotting of the concentration of ice-cream mixes.

licated, (a, b, c, and d) were prepared directly. These were stirred separately in the freezer at 0°C . until a constant value for basic viscosity was obtained. It took 90 minutes to reach the basic value of sample d.

In the case of mixes No. 2 and No. 3 only the most concentrated sample (d) was prepared. After the basic viscosity had been determined for this concentration (d), the mix was drawn from the freezer, weighed and diluted with cold water to the next concentration (c) and the process repeated to the lower concentrations (b and a). The table gives not only the concentrations as determined by analysis but also the basic viscosities and the calculated value of Θ , the Arrhenius constant, as well as the constant k . In Fig. 1 the viscosities are plotted logarithmically against the actual concentration.

*Expressed in number parts total solids to 100 parts water.

From the table and plot it is seen that straight line curves result, showing, as would be expected from the Arrhenius formula, that there is a definite relation between the logarithm of the viscosity and the concentration of the mixes. The viscosity values calculated for zero concentration (the values of k) vary from the theoretical. These variations are probably to be explained by the fact that in the mixes under experiment the weight concentration is only a rough approximation of the true molecular concentration. It seems reasonable, therefore, to conclude that the basic viscosity is a true fundamental value.

We have already stated that the viscosity of a freshly prepared mix has a lower value than the basic viscosity of the mix that has stood overnight. (9.11 cp to 36.21 cp). Additional experiments have shown that the basic viscosity of a mix shows no further change after standing for one week at

5° C., although, as would be expected, there is a marked increase in the apparent viscosity. When the mix is pasteurized it is, of course, heated above the melting point of the fats. If these do not harden rapidly upon cooling, it would be expected that the viscosity of the fresh mix would be low. The basic viscosity of a mix standing one day would therefore be higher than the viscosity of the freshly made mix. This increase can be explained in only one other way, which is to assume, at this stage, a certain degree of hydration of the milk solids, but Dahle and Caulfield¹ have measured the "bound water" of an ice-cream mix when freshly prepared and at intervals of 24, 48, and 72 hours. They find a constant low value. They conclude that the hydration of the protein of an ice-cream mix is complete before the ripening process is begun. If this is the case then the increase in the basic viscosity of the mix on standing, over that of the freshly prepared mix, must be due, not to the hydration of the protein, but to the solidification of the fats. The apparent viscosity must be the result of mechanical structure.

Conclusions

The existence of a measurable basic viscosity of ice-cream mixes has been demonstrated.

The change of value of this basic viscosity with concentration has been shown to follow the Arrhenius equation.

THE COALESCENCE OF AN UNFILTERABLE PRECIPITATE OF BARIUM SULFATE*

BY H. M. TRIMBLE[†]

Introduction

It has long been known that a precipitate which has just been thrown down from solution, and which is so fine as to pass through an ordinary filter, may be made filterable by digesting it for some time at an elevated temperature in contact with the mother liquor from which it was separated. Ostwald¹ was apparently the first to advance an explanation for this phenomenon. Under these conditions, he states, the smaller particles dissolve and the larger ones grow by deposition, so that finally a precipitate results which is sufficiently coarse to filter well. This explanation was an application of the principle enunciated by Sir William Thomson,² later Lord Kelvin, according to which the vapor pressure or solution pressure of a substance in the form of very small particles varies inversely as the size of its particles. Some work (soon to be published), carried out by the author with Professor S. Lawrence Bigelow indicated that, while it is undoubtedly true that the vapor pressure of a small particle is greater than that of a larger one, yet this difference is vanishingly small for particles of measurable size. It was found, too, that any transfer of material from smaller to larger particles due to such difference is exceedingly slow. By analogy it seemed that the rate at which larger crystals of a nearly insoluble substance will grow at the expense of smaller ones in contact with its solution must be very low; probably too low to account for the coalescence of precipitates as it occurs in ordinary analytical practice.

Evidence is not wanting to show that this is, indeed, the case. G. A. Hulett,³ in the course of a study of this very matter, added three grams of very finely pulverized gypsum to 250 cc. of a solution which had been saturated over large plates of this material and agitated the preparation gently at constant temperature. The concentration of the dissolved electrolyte was determined from time to time by measuring the electrical conductivity of the solution. The small particles were, on the average, about 0.3 microns in apparent diameter at the start of the experiment. The conductivity rose to a maximum almost immediately, and then fell slowly. At the end of 48 hours it had fallen nearly to the conductivity of a normally saturated solution; but it was only after nine days that this value was actually reached. Parallel

³ G. A. Hulett: Z. physik. Chem., 37, 385-406 (1901); 47, 357-367 (1904).

with this decrease of the conductivity, which indicated a decrease in the concentration of the solution, went the disappearance of the smallest particles. At the end of nine days they had disappeared completely, and the smallest particles then present were approximately two microns in diameter. Hulett concluded that above this size, the solubility of gypsum is no longer a function of particle size. It is noteworthy that equilibrium was approached very slowly during the latter part of this experiment. If we accept the explanation of coalescence which Ostwald advanced, it follows that the rate of elimination of the last of the smaller particles is very low.

Hulett found in similar experiments that barium sulfate behaved in the same manner as did gypsum. In particular he found that, at 25°C., its solubility is no longer a function of the size of its particles if these latter are larger than about 1.8 microns in diameter.

Von Weimarn¹ found that colloidal barium sulfate is converted to regular crystals in the course of time. Thousandth-normal solutions of barium thiocyanate and manganous sulfate were mixed in the cold, and the precipitate was allowed to stand quietly in contact with its mother liquor without stirring or shaking. His description follows:

"During the first few hours after the appearance of the opalescence the greater part of the precipitate consists of particles which seem to be spherical under the highest magnifications of the microscope. After twelve hours the part of the precipitate which has settled upon the bottom of the vessel consists of tiny crystals in the form of parallelepipeds of different sizes, and of aggregates of spherical particles (as seen under a magnification of 1500 times). After a month it is readily seen that the crystals have grown; but the aggregates of spherical particles still constitute an important part of the precipitate. It requires a half year for the aggregates to disappear almost completely; and at that time the precipitate consists of characteristic barium sulfate crystals."

The individual units in the aggregates of spherical particles cannot be seen in the photographs as given. It seems certain that they were very small.

If the colloidal material of this experiment was amorphous barium sulfate, it constituted an unstable phase in the precipitate. The difference in solution pressure between an unstable and a stable form of this substance is certainly greater than any such difference between particles of comparable sizes in either phase. The transfer of material in a system containing these two phases should be more rapid than in one which contains only crystals of different sizes. But von Weimarn holds that all matter, even in the colloidal state, is crystalline. If this is true, the system with which he worked was the same in nature as that which we are considering. The question cannot be decided by microscopic examination, since very small particles of any kind show up as tiny discs of light, quite without distinguishing features. No matter which view we take, however, the experiment furnishes direct

¹ P. P. von Weimarn: *Kolloid-Z.*, 3, 289-90 (1908).

evidence that the growth of larger particles of barium sulfate at the expense of smaller ones, at room temperature and without stirring, is a very slow process.

But for lack of space, various other observations of this kind might be cited. In every case, so far as the author is aware, the changes studied took place at or near room temperature. But digestions for the purpose of rendering an unfilterable precipitate filterable are invariably carried out at elevated temperatures. It seemed worth while, then, to determine whether the same results would be found at these higher temperatures.

Experimental Part

Obviously a precipitate can be made filterable by digestion only if all particles small enough to pass through the pores of the filter can be eliminated in this way. The average size of the pores in ordinary thick filter paper has been found to be¹ about 3.3 microns. This value was calculated from the permeability of this paper to water, and may or may not indicate the magnitude of the actual maximum pore size. A number of experiments were run, accordingly, to determine the size of the largest particles which will pass through such filter papers as are commonly used in quantitative analysis. Finely pulverized barium sulfate was suspended in water and this suspension was poured into filters made up in the usual way using three well-known kinds of filter paper. The part of the precipitate which passed through was collected and its particles were examined under the microscope. In every case particles as large as three microns in diameter were not at all uncommon, and some which were as large as four microns were found. The maximum pore sizes, then, must be very much as calculated from the permeability to water. It seems safe to set somewhat more than four microns as the size of the smallest particles which will certainly be retained by ordinary quantitative filter paper.

But a filter is by no means a sieve. Filter paper is a colloidal material which is usually negatively charged. As such it tends to hold barium sulfate particles of any size, since they are positively charged when prepared, as in quantitative analysis, by precipitation from dilute acid solutions of sulfates by the addition of barium chloride. Due to this and other causes its pores soon become clogged and its efficiency is thereby increased. Filters of other materials might be used in separating particles of different sizes; but at the best the retaining power of any given filter is only very imperfectly reproducible. While, then, filterability serves as a convenient practical criterion as to particle size, it is not a very certain or useful one. The direct measurement of particles with a microscope, using a filar micrometer, is much better. The unavoidable error which is involved may be reduced to a minimum by measuring a large number of particles from each precipitate which is examined. This method was used in the present study, supplemented by numerous tests as to filterability using filters of ordinary quantitative filter paper.

¹ "Third Report on Colloid Chemistry." Brit. Ass. Adv. Sci., L. p. 68 (1920).

Barium sulfate is perhaps more frequently digested to render it filterable than any other precipitate which is handled in quantitative analysis. Its low solubility should make the growth of larger particles at the expense of smaller ones very slow. But it is found in practice that a few hours digestion at a high temperature in the presence of a small amount of hydrochloric acid, without stirring, will render a precipitate of this substance readily filterable, provided it has been prepared in the proper manner. For this reason it seemed the most suitable substance for study. It was used in most of the experiments which are described below. The results have been confirmed, however, by experiments in which barium chromate, lead chromate, lead sulfate and calcium oxalate were used. The experiments had for their purpose to determine whether particles of these substances smaller than about four microns in average diameter can be eliminated from precipitates containing them by digestions such as are carried out in ordinary quantitative analysis.

Rhombohedral crystals of barium sulfate about ten to twenty five microns in length were prepared by slow addition of barium chloride solution to a hot dilute solution of sulfuric acid containing a small amount of hydrochloric acid. Small particles were prepared for the first experiments by crushing this material in an agate mortar, suspending the powder in a large quantity of water and pouring off the suspension which had not settled out after standing quietly for one or two minutes. These particles were recovered by allowing the suspension to settle for about an hour and then pouring off the supernatant liquid. This left a heavy suspension which was used at once in an experiment. It was impossible to filter these precipitates clear. As measured under the microscope the individual particles were found to be between one and four microns in diameter, the smallest ones being vastly in the majority. Particles smaller than one micron were few.

About one-tenth gram of larger rhombohedral crystals was added to a portion of this suspension which contained one fourth to one half gram of material. The volume was then made up to about 500 cc., hydrochloric acid was added, and the preparation was divided into approximately equal portions after stirring it up. One portion was then allowed to digest at about 95° to 100°C. without stirring. The other was heated under the same conditions, except that it was stirred during the progress of the experiment by means of a mechanical stirrer. Water and a little hydrochloric acid were added from time to time as needed to replace the liquid lost by evaporation. Nine experiments were run in this manner. The precipitates which were digested without stirring filtered clear after two to four hours in every case. Microscopic examination showed that the small fragments which were introduced at the start had, in these experiments, formed aggregates. Their average size remained almost unchanged. The other preparation which had been digested with stirring would not filter clear even after three days or more. Microscopic examination showed that the smallest particles had disappeared during this digestion. No particles smaller than about two microns in diameter could be found in the precipitates. The size of the larger rhombohedral crystals was not appreciably changed in any case.

In ten similar experiments suspensions of barium sulfate which had been prepared by mixing normal solutions of barium chloride and sulfuric acid in the cold were used. Such volumes of the solutions were taken that about one gram of barium sulfate was thrown down. The particles which formed were all very small; none of them being larger than one micron in apparent diameter. The larger rhombohedral crystals which were present during the digestions did not change appreciably in size. The portions which were digested without stirring coalesced more slowly than before; but five to ten hours sufficed to render the precipitates filterable in every case. At this stage the particles were again aggregated together. The aggregates were all made up of unit particles two microns or less in diameter. In the portions which were digested with stirring all the smallest particles disappeared, so that at the end of three days the smallest ones present were two microns or more in diameter. The precipitates could not be filtered clear in any case, though four digestions were carried on for two weeks in the hope of attaining this end. It was, of course, impossible to determine whether or not the total amount of fine precipitate had diminished. Even at the end of two weeks digestion the smallest particles present were still about two microns in diameter.

Numerous experiments were carried out in the attempt to grow crystals at the expense of finely divided and apparently amorphous barium sulfate at elevated temperatures. The precipitates were prepared by mixing in the cold equivalent volumes of barium chloride and sulphuric acid. The concentrations of these solutions varied between one hundredth normal and twice normal. The amount of the precipitate at the start, the concentration of hydrochloric acid at the start and the time of digestion were all varied between rather wide limits. The digestions were carried out both with and without stirring, but large crystals were not introduced in any case. The precipitates were examined from time to time with a microscope, using a magnification of 1000 diameters, but no crystals which were recognizable as such were ever found. The largest particles before digestion were less than one micron in diameter. After digestion for some days they were between two and three microns in diameter, on the average. Those precipitates which were digested without stirring became filterable after a day or two in some cases. In others they could not be made filterable. None of those which were digested with stirring were rendered filterable.

Ammonium acetate and sulfuric acid were introduced in a number of experiments instead of hydrochloric acid. Digestions were carried out both in the presence and in the absence of large rhombohedral crystals of barium sulfate. It was hoped that these solvents might aid in the growth of larger particles at the expense of smaller ones. This hope was realized, in that all particles smaller than about two microns disappeared after a few days digestion. Particles of this size, however, could not be eliminated by further digestion.

It seemed that any loss of matter by the smaller particles to larger ones in these experiments might be revealed if the total quantity of the former was very small. In some further experiments, therefore, just enough barium

chloride and sulfuric acid were added to distilled water to give a faint opalescence. The particles which were present at this stage were not measured. Large rhombohedral crystals were then introduced and the preparations were digested hot, with stirring. Hydrochloric acid, ammonium acetate and sulfuric acid were introduced in different experiments as solvents. After two or three days digestion the precipitates were collected and studied. The very small particles which at first formed the opalescence had disappeared and in their place were many particles about two microns in diameter. The small particles were not removed entirely, as might have been expected. The findings of the earlier experiments were thus confirmed.

Discussion of Results

This work shows that particles of barium sulfate larger than two microns in apparent diameter cannot be made to go over to yet larger ones, even by protracted digestion at a high temperature. Measurements of large crystals before and after digestion, too, showed that their growth is inappreciable. It follows, then, that the coalescence of an unfilterable precipitate which renders it filterable cannot be explained in terms of the growth of larger particles at the expense of smaller ones. But we must still account for it, for the change undoubtedly takes place. The fact that, on digestion without stirring, aggregates form; while they do not form when the digestion is accompanied by stirring shows the way to the answer. In view of all the facts the best explanation seems to be as follows: The precipitated particles when allowed to settle come into intimate contact with one another and form aggregates which adhere rather firmly. As the digestion proceeds barium sulfate, either from the still supersaturated solution or from the dissolving of very small particles, deposits upon these aggregates and cements them together. This effect is enhanced when the solution is allowed to cool. In this way large bodies which will not pass through the pores of a filter are formed.

On the other hand, when the digestion is accompanied by stirring all the crystals present grow alike at the expense of any material which may be separating from solution. There is no opportunity for cemented aggregates of crystals to form. Thus, while larger crystals do grow at the expense of smaller ones, if the latter are less than about two microns in diameter, the amount of such growth is very small; so small, indeed, that it could not render filterable a precipitate which is otherwise unfilterable.

Summary

The results of this study show that the solution pressure of barium sulfate at about 100°C. ceases to be a function of particle size for particles larger than about two microns in diameter. The coalescence of barium sulfate precipitates on digestion which renders them filterable cannot be adequately explained in terms of the growth of large particles at the expense of smaller ones. It is brought about, rather, by the collection of particles into relatively large aggregates, followed by the cementing together of the unit particles in the aggregates.

STUDIES ON THE SYSTEM LIME-ALUMINA-SILICA. THE COMPOSITION $8\text{CaO} + \text{Al}_2\text{O}_3 + 2\text{SiO}_2$

BY W. C. HANSEN, W. DYCKERHOFF, F. W. ASHTON AND R. H. BOGUE^{1, 2}

Introduction

Jänecke³ in 1912 reported that he had obtained a compound of the composition $8\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$ in the ternary system $\text{CaO}-\text{Al}_2\text{O}_3-\text{SiO}_2$. Rankin and Wright⁴ disagreed with him and in their complete study⁵ of the system found no evidence to substantiate his belief. Wetzel⁶ studied polished sections of Jänecke's preparations by etching with acids and concluded that the phase considered by Jänecke as the $8\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$ compound was a primary phase separating out of a glass and, therefore, did not have the composition of the preparation *i.e.*, $8\text{CaO} + \text{Al}_2\text{O}_3 + 2\text{SiO}_2$. The descriptions of this phase given by Jänecke and by Wetzel indicated, however, that it was different from any described by Rankin and Wright.

Upon making a comprehensive study of the system $\text{CaO}-\text{Al}_2\text{O}_3-\text{SiO}_2$ one of us⁷ found a crystalline phase that differed in appearance from those ordinarily found⁸ in portland cement or preparations of CaO , Al_2O_3 , and SiO_2 . This phase was formed by heating the mixtures in an oxyhydrogen flame, a method described in a previous publication.⁹ A study of the new phase was made and the conclusion reached that it had a composition of $8\text{CaO} + \text{Al}_2\text{O}_3 + 2\text{SiO}_2$. The results of this study, however, agreed with those of Jänecke only as to the composition of this phase. The conditions for the formation of the "compound" and the other properties associated with it were reported to be different from those attributed to it by Jänecke.

The phase in question was found also by the rest of us,¹⁰ using the method employed by Dyckerhoff. A study of this phase gave results which seemed, however, to be opposed to the existence of the ternary compound.

An opportunity presented itself for the four of us to work together for a few weeks, and the results of this cooperative investigation are presented in the present report.

Experimental Part

Materials used.—The raw materials used in this investigation were calcium carbonate, alumina, silica and ferric oxide. The chemical analysis¹¹ of each is given below:

	Calcium Carbonate	Alumina	Silica	Ferric Oxide
CaO	55.55	0.02	0.02	—
CO ₂	43.63	—	—	—
Al ₂ O ₃	0.01	98.35	0.50	—
SiO ₂	0.03	0.00	99.37	—
Fe ₂ O ₃	—	0.10	0.03	99.15
FeO	—	—	—	nil
MgO	0.07	0.08	—	—
SO ₃	0.00	0.00	—	nil
P ₂ O ₅	0.02	—	—	—
Cl	0.04	0.01	—	—
Loss on ignition	43.97	1.55	0.11	0.93

Heat treatments.—The preparations were made by first mixing the raw materials in the proper proportions on paper and decarbonating in an electric muffle furnace in a platinum dish. The mixture was then made into a stiff paste with water on a glass plate and kneaded for about thirty minutes to insure homogeneity. The paste was rolled on waxed paper into rods about the size of a lead pencil and these when dry were held in the oxy-hydrogen flame until a good sized drop formed. This drop was melted off and allowed to fall on platinum foil and cool in the air. Several grams of the 8CaO + Al₂O₃ + 2SiO₂ composition were prepared in this way and used for the examinations and experiments described below.

A number of the drops were powdered and a sample analysed to ascertain if the ratio of the components had remained constant during the burning. The results of this analysis¹ are compared below with the theoretical composition.

	Analysis of drops per cent	Theoretical 8CaO + Al ₂ O ₃ + 2SiO ₂ composition per cent
CaO	66.73	66.76
Al ₂ O ₃	15.25	15.23
SiO ₂	17.86	18.00

Thin sections were made of some of the drops and examined with a petrographic microscope. Fig. 1 is a photomicrograph of one of these sections taken under crossed nicols. The fiber-like structure illustrated in this figure was found to be very abundant in all of the drops examined indicating that it might be due to a ternary compound. Some of the drops were powdered and examined microscopically; glass and CaO could then be identified. Com-

¹¹ Analyses by H. C. Strecker.

plete optical measurements were not obtained on the fibers because of the difficulty of finding good individual crystals but the bi-refraction and mean index were very close to the values given by Wright for $3\text{CaO} \cdot \text{SiO}_2$.

This indicated that the aggregates might be $3\text{CaO} \cdot \text{SiO}_2$. If this were the case, two other phases, $2\text{CaO} \cdot \text{SiO}_2$ and $3\text{CaO} \cdot \text{Al}_2\text{O}_3$, should appear if the preparations were treated in such a way as to bring about equilibrium.

FIG. 1

Composition $8\text{CaO} + \text{Al}_2\text{O}_3 + 2\text{SiO}_2$
Nicols crossed, $\times 85$

Characteristic fiber-like structure observed in the drops prepared
in the oxyhydrogen flame.

From the diagram given by Rankin and Wright,⁵ page 40, a part of which is given in Fig. 2, it may be seen that in such a composition $3\text{CaO} \cdot \text{SiO}_2$, $2\text{CaO} \cdot \text{SiO}_2$ and $3\text{CaO} \cdot \text{Al}_2\text{O}_3$ exist together at equilibrium at temperatures up to 1455° .¹² At that temperature the first liquid appears. Therefore, to obtain such an equilibrium and complete crystallization as rapidly as possible a temperature just below 1455° should be used.

A treatment which would establish equilibrium if the crystals were $3\text{CaO} \cdot \text{SiO}_2$ should tend to establish equilibrium and cause the preparations to become more nearly homogeneous if they were a ternary compound.

The following experiments were performed in an effort to establish equilibrium in these preparations.

(1) Two drops were wrapped in platinum foil, suspended in the quenching furnace¹³ and heated to about 1600° at which temperature they were held for one hour. They were then cooled to 1450° during one and one-half hours and held at 1400° - 1450° for one and one-half hours.

¹² All temperatures discussed in this paper are in degrees centigrade.

¹³ See Hansen and Bogue: J. Am. Chem. Soc., **48**, 1261 (1926) for a description of this furnace and temperature measurements.

The two drops fused together during the treatment. The charge ~~was~~ sawed in two with a diamond saw, a thin section and powder were examined microscopically but no marked changes could be observed.

(2) A charge of powdered drops was heated in the same way to about 1600° , held there for one hour, and cooled to 1450° during one hour. It was

FIG. 2
Section of diagram of System $\text{CaO} - \text{Al}_2\text{O}_3 - \text{SiO}_2$ (Rankin and Wright).

FIG. 3
 Nicols crossed, $\times 95$
 Photomicrograph of charge 2, which was held at 1400° - 1450° for 15 hours. Note the higher birefractance of edges of large crystals showing the formation of $2 \text{ CaO} \cdot \text{SiO}_2$.

then held at 1400° - 1450° for fifteen hours. In this charge the amount of the fibrous aggregates had decreased as shown in the photomicrograph of a thin section in Fig. 3. The edges of many of the large crystals that remained had a much higher birefractance than did their interior as is brought out clearly in the figure. This indicated that the liquid present during the treatment was reacting with the aggregates to form $2\text{CaO} \cdot \text{SiO}_2$. It was evident, however, that the reaction was still incomplete and that equilibrium had not been established.

FIG. 4
Nicols crossed $\times 105$

Photomicrograph of a thin section of charge 3, heated 30 hours at 1400° - 1450° . Note the fine-grained structure with only an occasional large crystal.

(3) A charge of powdered drops was then heated to about 1600° for three hours, cooled to 1450° during one hour and held there at 1400° - 1450° for thirty hours. This charge, Fig. 4, was evidently at or very close to equilibrium as only a very few fibrous aggregates were present and the section seemed to be made up of a nearly uniform mixture of grains of $3\text{CaO} \cdot \text{SiO}_2$, $2\text{CaO} \cdot \text{SiO}_2$ and $3\text{CaO} \cdot \text{Al}_2\text{O}_3$. The refractive indices of these compounds were measured on the powder by the immersion method to verify the observations made upon the thin section.

The above tests demonstrated clearly that these preparations were composed, at equilibrium, of the three compounds $3\text{CaO} \cdot \text{SiO}_2$, $2\text{CaO} \cdot \text{SiO}_2$ and $3\text{CaO} \cdot \text{Al}_2\text{O}_3$ instead of one ternary compound.

The possibility remained, however, that a ternary compound or solid solutions might exist in this region of the system at high temperatures and

decompose at lower temperatures giving at equilibrium the above mentioned compounds. If this were the case, X-ray studies might reveal the presence of such phases.

*X-ray Studies*¹⁴—In other studies in this laboratory pure $3\text{CaO} \cdot \text{SiO}_2$, $3\text{CaO} \cdot \text{Al}_2\text{O}_3$ and $\beta_2\text{CaO} \cdot \text{SiO}_2$ were prepared by burning the desired composition in a gas-fired or an electric furnace and regrinding and reburning

FIG. 5
Analyser out $\times 65$
Composition $8\text{CaO} + \text{Fe}_2\text{O}_3 + 2\text{SiO}_2$. Note the fiber-like structure similar to that in Fig. 1.

until the product was homogeneous as shown by a microscopic examination. To obtain $\beta_2\text{CaO} \cdot \text{SiO}_2$ about one-half per cent of boric acid was added to the raw materials. A part of this is volatilized during the burning but that which remains is sufficient to prevent the beta to gamma inversion.

A mechanical mixture of the three compounds $3\text{CaO} \cdot \text{SiO}_2$, $3\text{CaO} \cdot \text{Al}_2\text{O}_3$ and $\beta_2\text{CaO} \cdot \text{SiO}_2$ was made up in equimolecular proportions which results in the composition $8\text{CaO} + \text{Al}_2\text{O}_3 + 2\text{SiO}_2$. The X-ray spectrum of this mixture was photographed on the same film as the spectrum of a powder made from the fused drops previously described. The spectrum of the latter preparation showed a few lines that the mechanical mixtures did not. These were found to be due to CaO ¹⁵.

In Table I are given the planar spacings and relative intensities of the lines found in the spectra of the $8\text{CaO} + \text{Al}_2\text{O}_3 + 2\text{SiO}_2$ preparation, of CaO and of the mixture of the three compounds, $3\text{CaO} \cdot \text{SiO}_2$, $2\text{CaO} \cdot \text{SiO}_2$, and $3\text{CaO} \cdot \text{Al}_2\text{O}_3$.

¹⁴ The X-ray data presented here were obtained by E. A. Harrington using the powder method devised independently by A. W. Hull: *Phys. Rev.*, 10, 661 (1917), and by Debye and Scherrer: *Physik. Z.*, 17, 277 (1916).

24	0.900	1	0.896	1			$3\text{CaO} \cdot \text{Al}_2\text{O}_3$

The compounds causing each of the principal lines in the spectrum of the fused drops are listed in the last column of this table.

Since all lines in the spectrum of the fused preparation correspond to the lines in the spectra of the four compounds, and no shift in any of the lines or any appreciable change in the relative intensities could be detected, it seems to follow that no compounds other than those four are present and that no solid solution is present. The fibrous aggregates appear, therefore, to be one of these four compounds and their optical properties indicate that they are $3\text{CaO} \cdot \text{SiO}_2$.

The form in which the $3\text{CaO} \cdot \text{SiO}_2$ crystallizes from the drops seems to be dependent upon the conditions under which it is produced. In order to ascertain if it would be formed in the same way in other systems, the composition $8\text{CaO} + \text{Fe}_2\text{O}_3 + 2\text{SiO}_2$ was made up and drops prepared in the oxy-hydrogen flame. Fig. 5 shows a photomicrograph from a section of one of these drops. It may be observed that the same fiber-like crystals are obtained in this system. The birefracton and mean refractive index indicated also that they were $3\text{CaO} \cdot \text{SiO}_2$. This constitutes further proof that the formation of fibrous aggregates is not dependent upon Al_2O_3 and, therefore, is not a ternary compound nor solid solution containing CaO , Al_2O_3 and SiO_2 .

General Discussion

This investigation has been concerned with the study of a crystalline phase that appears to be different from any described by Rankin and Wright. This phase forms as fibrous aggregates when mixtures of the composition $8\text{CaO} + \text{Al}_2\text{O}_3 + 2\text{SiO}_2$ are heated at very high temperatures. The following points concerning this phase led one of us to believe that the ternary compound $8\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$ existed.

1. The abundance of the phase: some thin sections appeared to be composed almost entirely of these aggregates;
2. The form of the crystals: this appeared to be different from that of any of the equilibrium compounds;
3. The absence of predicted equilibrium compounds: the equilibrium to be expected according to the diagram of Rankin and Wright was not obtained when the preparations were heated for several days at 1200° .

By the experiments reported in this paper these aggregates have been broken up and preparations obtained which consisted of the three compounds $3\text{CaO} \cdot \text{SiO}_2$, $2\text{CaO} \cdot \text{SiO}_2$ and $3\text{CaO} \cdot \text{Al}_2\text{O}_3$. This was made possible by furnaces which permitted the preparations to be heated for long periods at temperatures above 1400° . Such treatment was not possible with the furnace available for the study previously reported⁷ and, therefore, the temperatures then used were not sufficient to establish equilibrium.

It has been shown by the experiments reported in this paper that these preparations, when at equilibrium, no longer contain the fibrous aggregates and that no one phase is present in such great proportions as were the aggregates in the original fused drops.

With respect to the abundance of the fiber-like phase, it is possible that several factors contributed to that appearance. Fig. 6 is a photomicrograph

under high magnification of a thin section of one of the original drops. There it may be seen that the fibrous crystals contain inclusions that could not be observed easily under lower magnifications. Likewise the X-ray method showed that the preparations contained $2\text{CaO} \cdot \text{SiO}_2$ and $3\text{CaO} \cdot \text{Al}_2\text{O}_3$ which could not be positively identified by the microscope.

FIG. 6

Nicols crossed, $\times 900$

Photomicrograph of a thin section of the original drops. Note the minute inclusions in the aggregates.

Summary and Conclusions

An investigation has been made of the composition $8\text{CaO} + \text{Al}_2\text{O}_3 + 2\text{SiO}_2$ with the intention of studying the evidence bearing upon the existence of a compound of that composition.

By using the oxyhydrogen flame for preparing the samples, a crystalline phase was obtained which differed in appearance from the phases ordinarily found in mixtures of CaO , Al_2O_3 and SiO_2 heated to temperatures up to 1600° .

By proper heat treatments it was found possible to bring these preparations to the equilibrium found to exist in this system by Rankin and Wright.

The birefracton, mean refractive index and X-ray spectrum of this phase were the same as those obtained for $3\text{CaO} \cdot \text{SiO}_2$.

The phase also forms in the composition $8\text{CaO} + \text{Fe}_2\text{O}_3 + 2\text{SiO}_2$ when treated in the same manner.

By use of high magnifications and the X-ray spectra of these preparations, they were shown to be inhomogeneous, containing other crystalline materials.

All of the evidence obtained in this study and presented here is opposed to the existence of a ternary compound of the composition $8\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$ stable in this system. This evidence likewise is opposed to the existence of solid solutions of the silicates and aluminates in this part of the system.

It is concluded that the fiber-like crystals previously reported by some as $8\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$ are $3\text{CaO} \cdot \text{SiO}_2$.

AQUEOUS SOLUTIONS OF SODIUM SILICATES. VII. SILICATE IONS.

ELECTROMETRIC TITRATIONS: DIFFUSION: COLORIMETRIC ESTIMATION.

BY R. W. HARMAN

Introduction

From the papers already communicated by the author on the subject of aqueous solutions of varying ratio $\text{Na}_2\text{O}:\text{SiO}_2$, it is seen that the existence of definite silicate ions in these solutions rests on three main sources of evidence, viz.

(1) Conductivity measurements¹ resulted in the finding of a much greater conductivity for ratios up to 1:2 than could result alone from such a proportion of NaOH formed by hydrolysis as measured by the E.M.F. method. Above ratio 1:2, where the OH ion concentration is very low, the sodium ion accounts for only about one-half the conductivity found. The only way to account for the conductivity is to postulate the existence of silicate ions with mobilities ranging from 40-60 approximately. Moreover, the equivalent conductivity calculated from the concentration of sodium, hydroxyl and silicate ions, as found from F. Pts., OH and Na ion measurements, and their respective mobilities, agree well with the experimentally determined conductivity results.

(2) The most direct and conclusive evidence so far put forward to show that the silica in aqueous solutions of these ratios carries an electric charge is obtained from the results of transport number experiments.² There it was shown by the author that V_{sil} is 0.16 for ratio 1:1, 0.41 for ratio 1:2, 0.46 for 1:3 and 0.59 for 1:4, when calculated on the basis that the T. N. of the silicate is given by

$$\text{T.N. silicate} = \frac{\text{total change in weight of SiO}_2}{N \times (\text{wt. of SiO}_2 \text{ equivalent to Ag deposited in coulometer})}$$

where N = ratio. Whether this basis of calculation is correct or not these transport number experiments prove that quite a fair proportion of the current, at least one-half in the higher ratios, is carried by the silica. Since the possibility of adsorbed OH ions on the silica giving the necessary charge to the silica, has been shown to be remote and indeed most improbable³, the only conclusion is that the silica must exist as ions. The relatively high mobility of these charged silica particles as deduced from conductivity and transport number results, is also contrary to that expected from colloidal aggregates with OH ions adsorbed thereon.

² Harman: J. Phys. Chem., 30, 359 (1926).

³ Harman: J. Phys. Chem., 31, 355 (1927).

(3) A third very weighty argument appears when we consider the result of hydrolysis experiments along with freezing point lowering results. In the paper on osmotic activity¹ it was shown that the only possible way to account for the high osmotic activity of these ratios in aqueous solution was to accept the existence of silicate ions. The conductivity of the sodium ions and of the hydroxyl ions as found by E.M.F. experiments of Na ion and OH ion activities, together account for only a fraction of the total ion concentration as determined by vapour pressure and freezing point lowering. The non-accordance is quite beyond the bounds of experimental error, nor could it be accounted for by the assumptions underlying the laws governing ideal solutions. The higher the ratio the wider the divergence, so that in 1:3 and 1:4 more than half the crystalloidal content has to be accounted for by the silica in the most dilute solutions. Whether this is due to the complex silica aggregate breaking down into simpler silicate ions, or to the disintegration of an ionic micelle, or to crystalloidal H_2SiO_3 ionising, or to all these phenomena, can not be discussed fully at present. The fact remains however, of the existence of a very large proportion of "crystalloidal" silica in solution.

The existence of crystalloidal silica and silicate ions in aqueous solutions seems therefore firmly established, and there now remains the problem of the nature and composition of the ions and the proportions in which they exist. In the solution of this problem the nature and composition of the salts giving rise to these ions furnish a good guide, and help to narrow down the possibilities.

From the investigation of the ternary system² $\text{Na}_2\text{O} : \text{SiO}_2 : \text{H}_2\text{O}$ at 25°C we have seen that the ratios 1:1 and 1:2 only are definite salts. Ratio 1:1 is the metasilicate, Na_2SiO_3 , crystallising with 9, 6, and 2.5 aq., the existence of which has been long established in spite of the difficulty of its crystallisation and the confusion which till now has existed concerning its hydrates.

A certain amount of evidence that these two ratios 1:1 and 1:2 are definite salts is also forthcoming from consideration of the curves where conductivity, hydroxyl ion concentration, sodium ion concentration, and the van't Hoff factor "*i*" from freezing points are severally plotted against the ratio, distinct changes of direction at these points being evident. It was also seen from consideration of freezing point results³ that the existence of salts corresponding to ratios 1:3 and 1:4 was very unlikely. From the diagram of the ternary system $\text{Na}_2\text{O} : \text{SiO}_2 : \text{H}_2\text{O}$ (loc. cit.) the fact that the solubility of the definite salt 1:2 extends to the region 1:3 and 1:4 seems to indicate also that salts corresponding to 1:3 and 1:4 are unlikely. Ratio 1:2 may be either a salt of the formula NaHSiO_3 or $\text{Na}_2\text{Si}_2\text{O}_5$. It is not proposed to give here all the evidence for and against these two salts, except to state that (1) Morey⁴ has obtained $\text{Na}_2\text{Si}_2\text{O}_5$ from melts at high temperatures over 400°C but not from solutions at ordinary temperatures (2) the only one authentic case of a

disilicate occurring naturally is *rivaite*¹, and that in small amounts from Vesuvius (3) the author's results on freezing point lowering (loc. cit.) would seem to indicate NaHSiO_3 .

With the object of obtaining more experimental data on the subject and of attempting to obtain further insight into the constitution and concentration of crystalloidal silica, of silicic acid or acids and of silicate ions, experimental work was commenced on electrometric titrations, and on diffusion and on colorimetric determination of the silicate ion. Although only a few results have so far been obtained, their nature is sufficiently important to warrant publication at this stage.

The silicates used, their preparation nomenclature etc. are the same as described in previous communications on this subject by the author.

Electrometric Titrations and Dissociation Constants of H_2SiO_3

While attempting to calculate the dissociation constants of H_2SiO_3 from hydrolysis data it was thought that electrometric titrations would probably afford a more direct and accurate method of calculation. Only a few experiments have so far been carried out, and, while admitting that this section of the work is far from complete, it is thought that the results are sufficiently instructive and interesting to be included here.

Experimental

A dilute solution of ratio 1:1 was put in the hydrogen electrode vessel; hydrogen was bubbled through until the E.M.F. became steady; then small, measured quantities of standardised HCl solution were run in from a burette, and the E.M.F. noted after each addition of HCl . The hydrogen was kept bubbling through the electrode vessel during the whole experiment.

Results

Two such experiments only, have so far been carried out,—

(1) 0.1 N. HCl added to 0.1 N. Na_2SiO_3 .

(2) 1.219 N. HCl added to 0.2 N. Na_2SiO_3 .

In both, when the E.M.F. observed is plotted against the amount of HCl added as in Fig. 1, there is a small unmistakable drop of E.M.F. in the neighbourhood of 0.9250 volts, i.e. at point B in the figure, followed by a large and sudden drop from 0.8000 volts to 0.4000 volts.

The mid-point A of the large drop comes at 0.6005 volts with 0.1 N. Na_2SiO_3 , and at 0.6000 volts with 0.2 N. Na_2SiO_3 . The neutral point of water is at 0.7000 volts. (N. KCl calomel cell used).

The amount of HCl added, corresponding to point A, is equal to the calculated amount just sufficient to neutralize all the sodium in solution, while the amount of HCl added is, in both cases, at the mid-point B of the smaller drop, about one-half that corresponding to point A. This is good evidence of the existence of the acid metasilicate NaHSiO_3 .

From these two curves we conclude that H_2SiO_3 ionises in two stages,—

(1) $\text{H}_2\text{SiO}_3 \rightleftharpoons \text{H}^+ + \text{HSiO}_3' \dots \dots (k_1)$.

(2) $\text{HSiO}_3' \rightleftharpoons \text{H}^+ + \text{SiO}_3'' \dots \dots (k_2)$.

¹ Zambonini: Atti. Accad. Sci. Nap., 12, No. 12, p. 16 (1912).

Point B corresponds to equation (2), and at that point the following equilibrium exists,—

Point A corresponds to equation (1) and at that point the main equilibrium is

If the fall in E.M.F. at point B had been more definite, i.e. larger and sharper, then it would have been possible to calculate k_2 , the second dissociation constant of H_2SiO_3 therefrom with accuracy; as it is, it has been considered more prudent to omit assigning any definite value to k_2 until further work has been done with this specific point in view.

FIG. 1

First Dissociation Constant k_1

Point A₂, E.M.F. = 0.6000 volts (Fig. 1, curve 2.).

Conc. Na_2SiO_3 = 0.1 molar.

pH = 5.33. $[\text{H}^+] = 0.47 \times 10^{-5}$. $[\text{HSiO}_3'] = 0.47 \times 10^{-5}$.

$[\text{H}_2\text{SiO}_3]$ equals 0.1 m nearly; assuming, for which there is good reason given later, that the H_2SiO_3 is not colloidal,

Then,—

$$\begin{aligned} [\text{H}^+] \times [\text{HSiO}_3'] &= k_1 \cdot [\text{H}_2\text{SiO}_3] \\ &= \frac{(0.47 \times 10^{-5})^2}{0.1} \\ &= 2.2 \times 10^{-10}. \end{aligned}$$

For curve (1), Fig. 1, conc. Na_2SiO_3 equals 0.05m, and E.M.F. = 0.6005 volts, i.e. $[\text{H}^+] = 0.46 \times 10^{-5}$, hence, $k_1 = 4.2 \times 10^{-10}$.

An attempt was also made to titrate electrometrically NaOH and silicic acid, but here it is not of much use to begin with silicic acid or so-called

silicic acid prepared by dialysis, as this must necessarily be almost completely colloidal.

Instead, a dilute solution, $0.2 N_w$, of one of the ratios rich in silica, viz. 1:4, was taken and 10 N. NaOH added, the E.M.F. being measured after successive additions of measured quantities of NaOH, (the NaOH being added in drops.).

FIG. 2

The result is shown graphically in Fig. 2 where the E.M.F. observed is plotted against the quantity of NaOH added. This curve is different from that of OH ion concentration against ratio,¹ because there the sodium was kept constant while here the SiO_2 is being kept constant.

We note that the E.M.F. rises very rapidly until just beyond ratio 1:2, but only slightly and irregularly after that, until at 2:1 a fairly constant value is obtained.

It is doubtful however, whether the mixture reaches equilibrium in so short a time, and during the titration a break of three hours was made. At the end of this three hours, the E.M.F. had fallen until the value was almost

¹ Harman: J. Phys. Chem., 30, 1100 (1926). Fig. 2.

the same as at 1:1. This is indicated at point X on the figure. On further addition of NaOH the E.M.F. again increased to a constant value.

We cannot conclude much from this one curve alone, except that,—

(1) the mixture of silicate and NaOH does not reach equilibrium immediately, a conclusion already arrived at from conductivity measurements.

(2) the OH ion concentration of ratio 2:1 is not much greater than that of 1:1; this has already been noticed in the paper on hydrolysis.

Calculation of Dissociation Constants of H_2SiO_3 from Hydrolysis Data

One would expect metasilicic acid, H_2SiO_3 , the dibasic acid which forms the metasilicate NaSiO_3 , to ionise in two stages, and indeed there is evidence of its so doing from the electrometric titrations of Na_2SiO_3 against HCl just described.

Considering the hydrolysis of Na_2SiO_3 in two stages we can calculate the primary and secondary dissociation constants of H_2SiO_3 in the following manner.

Secondary Dissociation Constant k_2

where x = fraction hydrolysed, and α_1 , α_2 and α_3 the respective degrees of ionisation. If we put $\alpha_2 = \alpha_3 = 1$, i.e. NaOH and NaHSiO_3 completely dissociated, and take the values given for OH and Na ion concentrations from the E.M.F. measurements already communicated for x and α_1 respectively we get,—

$$k_2 = \frac{[\text{H}^+] \times [\text{SiO}_3'']}{[\text{HSiO}_3']}$$

Hence,—

$$\frac{K_w}{k_2} = \frac{x^2}{(1-x)c} - \frac{\alpha_1^2}{\alpha_1}$$

N_w	conc. m	x	α_1	K_w/k_2	k_2
0.1	0.05	0.414	0.03	195.0	0.51×10^{-16}
0.05	0.025	0.440	0.11	125.7	0.80
0.02	0.01	0.465	0.75	53.89	1.86
0.01	0.005	0.556	0.10	139.3	0.7
				Mean =	0.97×10^{-16}

Product of Dissociation Constants, $k_1.k_2$.

Considering the second stage,—

we get,—

$$k_1 = \frac{[\text{H}^+] \times [\text{HSiO}_3']}{[\text{H}_2\text{SiO}_3]}$$

Combining equations (1) and (2),—

$$[\text{H}^+]^2 \times [\text{SiO}_3''] = k_1.k_2 [\text{H}_2\text{SiO}_3].$$

Hence

$$\left(\frac{K_w}{2\alpha_2 X C} \right)^2 \cdot \alpha_1 (1-x) C = k_1.k_2.x C.$$

For conc. $C = 0.05M$, we get $k_1.k_2 = 8.3 \times 10^{-25}$.

$$\begin{aligned} \text{Hence } k_1 &= k_1.k_2 / k_2 \\ &= 1.6 \times 10^{-10}. \end{aligned}$$

Comparison of Dissociation Constants of H_2SiO_3

	From electrometric titration	From hydrolysis
$k_1 . k_2$		8.3×10^{-25}
k_1	4.2×10^{-10}	1.6×10^{-10}
k_2		0.51×10^{-16}

Silicate Ions

Hitherto the silica in solution has usually been regarded as wholly colloidal in nature, whether a solution of an alkali silicate or of silicic acid has been the subject of investigation. In view of the fact that the present investigations indicate that in some cases the silica is almost wholly crystalloidal, it seemed most advisable to obtain some direct evidence of the presence of silicate ions. This has been done in two ways,—

- (1) colorimetrically.
- (2) by diffusion.

Colorimetric Estimation of Silica

Diénert and Waldenbulcke¹ describe a colorimetric test for crystalloidal silica depending on the formation of a greenish yellow silicomolybdate.

On adding 2 cc. of a 10% solution of ammonium molybdate and 4 or 5 drops of a 50% solution of H_2SO_4 to a silicate solution, a yellow colour forms immediately in the cold, which deepens for 10 minutes or so and then remains constant for several hours. The test is perfectly quantitative in dilute solution.

The mechanism of the reaction involved does not seem to be very clearly understood as yet. W. Asch² has shown the existence of the two salts,— $2\text{Na}_2\text{O}.\text{SiO}_2.12\text{MoO}_3.\text{aq.}$ and $1.5\text{Na}_2\text{O}.0.5\text{H}_2\text{O}.\text{SiO}_2.12\text{MoO}_3.\text{aq.}$, and that in these salts the silicic and molybdic acids form a complex ion.

Many compounds of silica besides the simple silicates investigated here, e.g. K_2SiF_6 , give the test, but colloidal silicic acid, i.e. silicic acid prepared by lengthy diffusion does not give any colour, so that at best this colorimetric test can only be said to be a test for crystalloidal silica and not a test for any particular silicate ion, although probably the ion concerned is the simple silicate SiO_3 ion from metasilicic acid.

¹ Compt. rend., 176, 1478 (1923).

² "The Silicates in Chemistry and Commerce", 16 (1923).

The following Table I contains the results of this colorimetric test on ratios 2:1, 1:3 and 1:4. Ratio 1:1 was used as a standard, and the table shows the normality in terms of sodium content of ratio 1:1 required to give the same depth of colour as the normality cited for the other ratios, and the ratio of crystalloidal silica in 2:1, 1:3 and 1:4 to the crystalloidal silica in 1:1.

TABLE I

2:1	Std. 1:1	Crys. sil. in 2:1 Crys. sil. in 1:1	1:3	Std. 1:1	1:3 1:1	1:4	Std. 1:1	1:4 1:1
0.0005	0.00025	0.5	0.0005	0.0015	3.0	0.0005	0.0002	4.0
0.001	0.0005	0.5	0.001	0.0025	2.8	0.001	0.004	4.0
0.002	0.001	0.5	0.003	0.009	3.0	0.003	0.010	3.3
0.003	0.0015	0.5	0.005	0.014	2.8	0.005	0.016	3.2
0.004	0.002	0.5	0.007	0.018	2.6	0.007	0.022	3.1

It is seen that in very dilute solution, 0.005 N, ratio 1:4, contains as much crystalloidal silica as 0.002 N, 1:1, the normalities in accordance with the practice adopted in this investigation being expressed in terms of the sodium content. In other words, practically all the silica in ratio 1:4 exists in the crystalloidal state at a dilution of 0.005 N, or more correctly, ratio 1:4 contains 4 times as much crystalloidal silica as ratio 1:1 at this dilution.

Similarly at this dilution, all the silica in ratios 2:1 and 1:3 exist in the crystalloidal state.

As the solution gets more concentrated we see that ratio 1:4 no longer contains 4 times as much crystalloidal silica as ratio 1:1, indicating that in the more concentrated solutions some of the silica in ratio 1:3, and still more in ratio 1:4, passes into the colloidal state.

Hence in extremely dilute solutions of these ratios practically all the silica exists in the crystalloidal state, but with increasing concentration increasing amounts of colloidal silica are manifested.

Diffusion Experiments

The diffusion experiments were carried out with collodion membranes and with parchment paper. The collodion membranes were prepared in the form of a flask and were closed by a rubber stopper, through which a glass tube serving as a manometer passed, the whole being made airtight by coating the neck of the bag and the stopper with collodion.

It was found that all the ratios at all concentrations gave evidence of diffusion of silicate ions both with the collodion membrane and with parchment paper.

Diffusion was allowed to proceed for from 8-14 days (equilibrium being usually established in 6 or 7 days) and then the solutions inside and outside the membrane were analysed.

Results

With ratios 1:1 and 1:2 equal distribution of both sodium and silica was found to have taken place with a 0.3 N_w solution.

In ratio 1:3, with a solution approximately 0.2 N_w , after equilibrium had been established in a couple of days, there was an excess of silica within the membrane, thus showing that some of the silica in the original solution was colloidal.

More definite evidence of the existence of the silica as partly colloidal, partly crystalloidal, was obtained with a 0.3 N_w solution of ratio 1:4. The sodium content of the inside and the outside solutions was practically the same after 12 days diffusion, but there was 3.567% SiO_2 outside and 4.967% SiO_2 inside the membrane. Assuming the difference to be colloidal silica, i.e. non-diffusible silica, then in the original solution $1.4/4.2 = 1/3$ of its silica, was in the colloidal state.

It is not surprising that the general belief exists that silicic acid is almost wholly colloidal in solution when it is remembered, that it is prepared by dialysis, during which the crystalloidal constituent diffuses through the membrane and is discarded, leaving only the colloidal part. Any investigation into the nature of silicic acid should not, as has hitherto been the case, be confined to this colloidal proportion alone.

It was found that when a 1 N_w solution of ratio 1:1, to which a small excess of HCl had been added, was submitted to dialysis, silica rapidly diffused through the membrane, as much as 30% of the original SiO_2 content being diffusible.

Although this was observed and pointed out by Graham in his classic researches, its significance does not seem to have been generally recognised. When the outside water is changed continually, as in ordinary dialysis, a solution of silicic acid remained, which gave only the very slightest colour with ammonium molybdate and thus was practically all colloidal.

Conclusion

It has thus been shown conclusively that silicate ions exist in all the ratios up to 1:4, and in silicic acid itself. In 1:1 and 1:2 the silica is practically all crystalloidal in dilute solution, in ratios 1:3 and 1:4 increasing proportions are colloidal, and in extremely dilute solution, practically all the silica in any of these ratios here investigated exists in the crystalloidal state.

Summary

(1) Electrometric titrations of 0.1 and 0.2 N_w Na_2SiO_3 with 0.1 N and 1.219 N HCl, and 0.2 N_w Na_2SiO_3 , 1:4, with 10 N NaOH have been carried out.

(2) The curves obtained with Na_2SiO_3 and HCl are typical of dibasic acids, thus suggesting H_2SiO_3 as dibasic with salts NaHSiO_3 and Na_2SiO_3 .

(3) The primary and secondary dissociation constants have been calculated from hydrolysis results and from these electrometric titrations; $k_1 = 4.2 \times 10^{-10}$ and $k_2 = 0.51 \times 10^{-16}$.

(4) The amount of crystalloidal silica in ratios 2:1, 1:3 and 1:4 has been compared with that in ratio 1:1 in very dilute solution by means of the colorimetric test with H_2SO_4 and ammonium molybdate.

(5) In very dilute solution most of the silica in these ratios is crystalloidal, but increase of concentration and increase of ratio increase the colloidal content.

(6) Diffusion experiments through membranes of collodion and parchment paper indicate that most of the silica in ratios 1:1 and 1:2 is diffusible; about $\frac{2}{3}$ of the silica in 0.3 N_w 1:4, and about $\frac{1}{3}$ in 1.0 N_w H₂SiO₃ was crystalloidal.

(7) H₂SiO₃ is much stronger than hitherto supposed, due no doubt to the fact that when prepared by continuous dialysis the ionisable and diffusible portion is lost.

I wish to thank the Commissioners of the 1851 Exhibition for a Scholarship which has enabled me to carry out this investigation, and to express my gratitude to Professor Donnan at whose suggestion this work was undertaken, for his constant kindly interest and advice.

STUDIES ON THE TRANSFORMATIONS OF IRON IN NATURE

I. THEORETICAL CONSIDERATIONS

BY H. O. HALVORSON AND R. L. STARKEY*

Ever since man began to study nature his attention has been attracted by the transformations that take place. Since the transformations that attract the most attention are generally those that are accompanied by visible modifications, some of the changes of iron are particularly striking since here they are accompanied by the precipitation of the red oxides that are so plainly visible. These changes are interesting not only from a purely scientific standpoint but are of great economic importance, since they are responsible for the deposition of many formations of iron ore and are also concerned in the corrosion of iron, which in itself is of great economic importance.

Due to the great importance of these reactions, men from many different fields with widely different viewpoints have attempted to explain the agencies responsible for them. From these studies there have been developed various theories some of which definitely conflict. The pure chemist with slight appreciation of biology has presented explanations assuming no activity of biological agencies. On the other hand biologists have often attempted to explain the transformations with little regard for the chemical laws that must be obeyed even in biological processes. It is the object of these studies to indicate some of the fundamental chemical reactions governing the changes and the importance of some organisms in determining the courses of these reactions by their effects in modifying the physical environment. The fundamental equations developed in this paper shall be used in other papers to interpret the mechanism of the transformations.

It will simplify matters to consider first the equilibrium conditions that must be fulfilled in an inorganic solution containing iron in which no complex ions of iron are formed. In the following equilibrium conditions it is assumed therefore that no complex ions are formed. From the deductions arrived at by such a consideration it will be possible to predict in a qualitative way what influence the formation of complex ions will have upon the system. In a solution containing ferrous ions the oxygen of the air will oxidize some of these ions to the ferric form. This change can be indicated by the following reaction:

From the law of mass action we know that the equilibrium state will be expressed by the following equation:

$$(2) \quad \frac{[\text{A}_{\text{Fe}^{++}}]^4 [\text{A}_{\text{O}_2}] [\text{A}_{\text{H}^+}]^2}{[\text{A}_{\text{Fe}^{+++}}]^4 [\text{A}_{\text{OH}'}]^2} = K$$

*Department of Bacteriology and Immunology, University of Minnesota.

In this equation $A_{Fe^{..}}$ is the activity of the ferrous ions expressed in moles per liter, A_{O_2} the activity of the dissolved oxygen, A_H the activity of the hydrogen ions, etc. K is the equilibrium constant.

From the dissociation of water we can get the following equilibrium equation:

$$(3) \quad [A_H] [A_{OH}] = K_w$$

Combining (2) and (3) we get:

$$\frac{[A_{Fe^{..}}]^4 [A_{O_2}] [A_H]^4}{[A_{Fe^{..}}]^4} = K(K_w)^2$$

This can be rearranged as follows:

$$(4) \quad \frac{[A_{Fe^{..}}]}{[A_{Fe^{..}}]} \cdot [A_H] = \frac{K}{[A_{O_2}]^{\frac{1}{2}}}$$

If the solution is saturated with respect to ferric hydroxide the following equation will hold.

$$(5) \quad [A_{Fe^{..}}] [A_{OH}]^3 = K_1$$

$$(6) \quad \text{From (3) and (5)} \quad \frac{[A_{Fe^{..}}]}{[A_H]^3} = K''$$

$$(7) \quad \text{From (4) and (6)} \quad \frac{[A_{Fe^{..}}]}{[A_H]^2} = \frac{K'''}{[A_{O_2}]^{\frac{1}{2}}}$$

If the pressure of the oxygen is kept constant, then

$$(8) \quad \frac{[A_{Fe^{..}}]}{[A_H]^2} = C.$$

From the hydrolysis of ferrous ions we have the following reaction taking place:

The equilibrium equation will be

$$(9) \quad \frac{[A_{Fe}]}{[A_H]^2} = K_n [A_{Fe(OH)_2}]$$

$$(10) \quad \text{From (8) and (9)} \quad K_n [A_{Fe(OH)_2}] = C$$

It is evident from this that in a solution of ferrous iron in contact with atmospheric pressure of oxygen and solid ferric hydroxide the activity of the un-ionized ferrous hydroxide is fixed. This activity is independent of the pH but varies only with the oxygen pressure. This will be equivalent to the establishment of a solubility product for ferrous hydroxide even though the solution is not in equilibrium with the solid ferrous hydroxide. This will make it rather convenient to calculate the amount of ferrous iron that can remain in a solution at any pH.

The constant expressed in equation (9) above can be evaluated with sufficient accuracy for this theoretical consideration without much difficulty. In a dilute solution the concentration can be put equal to the activity without introducing much error. In a dilute solution of ferrous sulphate which has come to equilibrium the concentration of the ferrous ions can be put equal to

the total amount of iron in solution with no appreciable error. For the evaluation of the above-mentioned constant a series of solutions of ferrous sulphate were made up and allowed to come to equilibrium by standing open to the atmosphere for a period of four months. At the end of this time pH determinations were made of the solutions after which they were analyzed for total iron in solution. In order to determine the concentration of the iron, a sample of 2500 cc. was evaporated to dryness and the residue dissolved in a total volume of 50 cc. Two 20 cc. samples of this were taken and analyzed for iron by the oxidation with potassium dichromate, using the ferricyanide test for the end point. The pH was determined with a Leeds and Northrup Type K potentiometer, using a N/1 calomel half-cell as a standard electrode and a Bailey electrode for the hydrogen electrode. The results are given in Table I.

TABLE I

Conditions existing in solutions of ferrous sulphate in contact with air and in equilibrium with solid ferric hydroxide

Per cent FeSO ₄ in original solution. Approximate	pH	Moles of iron per liter. Final	Log Fe	Log $\frac{\text{Fe}}{[\text{A}_\text{H}]^2}$	$\frac{\text{Fe}}{[\text{A}_\text{H}]^2}$
.002	4.228	.0000188	5.274-10	3.730	5.38×10^3
.002	4.471	.00000672	4.827-10	3.769	5.88×10^3
.002	4.307	.0000134	5.128-10	3.742	5.52×10^3
.005	3.789	.000106	6.027-10	3.605	4.03×10^3
.005	3.893	.0000984	5.993-10	3.779	6.02×10^3
.005	3.787	.0001000	5.999-10	3.573	3.74×10^3
.008	3.677	.000180	6.261-10	3.653	4.50×10^3
.008	3.669	.000190	6.279-10	3.606	4.04×10^3
.008	3.677	.000180	6.261-10	3.653	4.50×10^3
.01	3.645	.000240	6.380-10	3.670	4.68×10^3
.01	3.623	.000242	6.383-10	3.629	4.26×10^3
				Average	4.77×10^3

If we assume that these solutions are sufficiently dilute to put the concentration of the iron as determined by titration to be equal to the activity, we can average the values obtained in the last column and we get

$$\frac{[\text{A}_{\text{Fe}}]}{[\text{A}_\text{H}]^2} = 4.8 \times 10^3.$$

The above assumption will introduce a slight error but the value is sufficiently accurate for this consideration. Experiments are now in progress in which the constant can be evaluated without this assumption. This will be published at a later date.

The concentrations of iron occurring in nature where precipitation of ferric iron is noted are extremely low. These solutions will be so dilute that not much error will be made by assuming that the concentration of ferrous iron is equal to the activity. The ratio of the activity of the ferrous ion over

the square of the activity of the hydrogen ion, which is approximately equal to 4.8×10^3 , will be used to interpret the mechanism of iron precipitation.

From this ratio it is possible to indicate what amount of iron can remain in solution at various hydrogen ion concentrations where no complex ions are formed. This is illustrated in Table II.

TABLE II
Ferrous ions held in solution at various pH values

pH	$[A_H]^2$	$A_{Fe^{++}}$	Parts of Fe^{++} per M.
3.0	$1. \times 10^{-5}$	4.8×10^{-3}	270.
4.0	$1. \times 10^{-8}$	4.8×10^{-6}	2.70
5.0	$1. \times 10^{-10}$	4.8×10^{-7}	.027
6.0	$1. \times 10^{-12}$	4.8×10^{-9}	.00027
7.0	$1. \times 10^{-14}$	4.8×10^{-11}	.0000027

In the last column are given the parts of ferrous iron that can remain in solution in a million parts of the solvent. The values given for pH of 3 and 4 are probably much too low since the activities here may be less than the concentration. By considering Table II and equation (1) above it can be seen that as the pH of the water is changed from 4 to 5 the ferrous iron will precipitate as ferric hydroxide. It also shows what the pH of the medium must be in order to hold any amount of iron in solution under atmospheric conditions.

From equation (4) when the pressure of the oxygen is kept constant we

know that
$$\frac{[A_{Fe^{+}}]}{[A_{Fe^{++}}]} \cdot [A_H] = K.$$

This constant can now be evaluated for the equilibrium condition under atmospheric conditions. We already have

$$(11) \quad \frac{[A_{Fe^{+}}]}{[A_H]^2} = 4.8 \times 10^3$$

The solubility product of ferric hydroxide has been determined with some degree of accuracy and is given in the literature¹ as follows:

$$[A_{Fe^{+}}] \cdot [A_{OH^{+}}]^3 = 1.1 \times 10^{-36}$$

From this and the dissociation product of water the product becomes:

$$(12) \quad \frac{[A_{Fe^{+}}]}{[A_H]^3} = \frac{1.1 \times 10^{-36}}{1 \times 10^{-12}} = 1.1 \times 10^6$$

Dividing (11) by (12) we get:

$$\frac{[A_{Fe^{+}}] \cdot [A_H]^3}{[A_H]^2 \cdot [A_{Fe^{+}}]} = \frac{4.8 \times 10^3}{1.1 \times 10^6} = 4.4 \times 10^{-3}$$

or
$$\frac{[A_{Fe^{+}}]}{[A_{Fe^{++}}]} [A_H] = 4.4 \times 10^{-3}$$

From this equation it is possible to calculate at different pH values what

¹ Cited from E. Müller in Landolt-Börnstein: "Physikalisch-Chemische Tabellen." 4th Ed. p. 1201 (1912).

the stable ratio of $\frac{[A_{Fe^{..}}]}{[A_{Fe^{...}}]}$ will be. Knowing the value for this ratio and the value of $[A_{Fe^{..}}]$ as indicated in Table II, it is possible to evaluate $[A_{Fe^{...}}]$ for different pH values. This is shown in Table III.

TABLE III
Amounts of ferric iron held in solution at different pH values

pH	$[A_{H^+}]$	$\frac{[A_{Fe^{..}}]}{[A_{Fe^{...}}]}$	Parts of $Fe^{...}$ per M.
3.0	1×10^{-3}	4.4×10^0	6.1×10^{-1}
4.0	1×10^{-4}	4.4×10^1	6.1×10^{-2}
5.0	1×10^{-5}	4.4×10^2	6.1×10^{-3}
6.0	1×10^{-7}	4.4×10^3	6.1×10^{-8}
7.0	1×10^{-8}	4.4×10^4	6.1×10^{-11}

It is evident from this table that in solutions having pH values of 4 or above that the total iron in the solution is practically equal to the ferrous iron in solution. As the solution becomes more basic the ratio of ferrous to ferric becomes greater.

The above deductions are made on the condition that the solution be in equilibrium with solid ferric hydroxide and be in equilibrium with atmospheric oxygen. It may be of interest to inquire into the state of affairs if the oxygen pressure is varied. Some light may be thrown on this by considering the original oxidation equation.

If this is a reversible reaction we can drive the reaction in either direction by varying the activity of the oxygen. The equilibrium equation is as follows:

$$\frac{[A_{Fe^{..}}]}{[A_{Fe^{...}}]} \cdot [A_{H^+}] = \frac{K}{[A_{O_2}]^{\frac{1}{2}}}$$

If we assume that the activity of the oxygen is unity at atmospheric pressure, we can say that where $[A_{O_2}] = 1$ then $K = 4.4 \times 10^{-3}$ and $\frac{[A_{Fe^{..}}]}{[A_{Fe^{...}}]} \cdot [A_{H^+}] = \frac{4.4 \times 10^{-3}}{[A_{O_2}]_P^{\frac{1}{2}}}$ where $[A_{O_2}]_P$ represents the difference between the activity of the oxygen at pressure p and at atmospheric pressure. In general the activity of the oxygen will vary directly as the pressure. By fixing our conditions so that the pressure of the oxygen is low, at equilibrium

$$\frac{[A_{Fe^{..}}]}{[A_{Fe^{...}}]} \cdot [A_{H^+}]$$

will have a greater value. This means that at a reduced oxygen pressure it is possible to maintain a greater ratio of $\frac{[A_{Fe^{..}}]}{[A_{Fe^{...}}]}$ at any pH than can be maintained under atmospheric conditions, since from (6) the $[A_{Fe^{...}}]$ depends only upon the pH. This will mean that by reducing the pressure of the oxygen,

keeping the pH constant, more ferrous iron will be formed and remain in solution. This is more easily seen from the equation $\frac{[A_{Fe}]}{[A_H]^2} = \frac{4.8 \times 10^8}{[A_{O_2}]_P^{\frac{1}{2}}}$

It is also evident that by increasing the pressure of the oxygen that the $[A_{Fe}]$ will have to diminish. It will do so by having the ferrous iron oxidized to ferric iron and precipitated as the hydroxide.

If the pH is not kept constant and the oxygen pressure is reduced the ferrous iron concentration will increase and the hydrogen ion concentration will diminish until the new equilibrium has been reached. If the oxygen pressure is increased the reverse change will take place.

Having the above reaction at equilibrium and then increasing the pressure of oxygen the reaction will change in the direction of the upper arrow. Decreasing the oxygen pressure the reaction will go in accordance with the lower arrow until a new state of equilibrium is reached.

If complex ions of iron are formed either as ferric or ferrous it will mean that there is more iron in solution than is indicated by the above equation involving its activities. The formation of the complex ions will remove a certain portion of the ions from the sphere of activity. The ability of these complex ions to increase the solubility of the iron above that indicated in Tables II and III will depend upon how effectively the complex ions can reduce the concentration of either the ferrous or ferric ions. If the concentration of the ferrous ions is reduced below the solubility of these ions no precipitate of the hydroxide will be formed and under these conditions it will be possible to maintain high concentrations of iron in solution even under basic conditions.

Summary

From a theoretical study of transformations of iron in pure solutions equations have been developed which indicate the relationships between the activities of the ferrous, ferric, and hydrogen ions and oxygen concentration. Measurements indicate that at reactions more alkaline than pH 5.0 very small amounts of ferrous iron will occur in solution under atmospheric conditions and even smaller amounts of ferric iron are soluble.

NEW BOOKS

An Introduction to Surface Chemistry. By Eric K. Rideal. 22 × 15 cm, pp. vii × 336. Cambridge: The University Press, 1926. Price: \$5.50. In the preface Donnan says: "The importance of an accurate study of the actions, equilibria, and structures which occur at the interfaces between homogeneous phases of matter is widely recognised at the present time. Thus a knowledge of these matters is required for a proper understanding of adsorption, the formation and stability of disperse or micro-heterogeneous systems (colloid sols and gels), catalysis, enzyme actions, etc., whilst the progress of research shows more and more clearly that the phenomena of life, i. e. the behaviour of cells and tissues, are intimately concerned with the actions occurring at surfaces, and that the effects produced by drugs, disinfectants, and other substances which profoundly affect the operation of cells and micro-organisms are largely due to surface actions."

"The great merit of Dr. E. K. Rideal's book lies in the fact that the author, whilst in no wise neglecting the thermodynamic treatment and its results, gives a very admirable account of this more recent and extremely important field of study. Since this is also the most promising line of advance in the investigation of disperse systems, Dr. Rideal's book can be most warmly recommended to all who are interested in colloid physics and chemistry. In the last two chapters the author gives a good introduction to the principal facts and theories of what is usually understood to-day as colloid chemistry, so that the reader is fully supplied with everything that is necessary for a thorough understanding of this subject. Every student and investigator of surface and colloid phenomena owes Dr. Rideal a warm debt of gratitude for his admirable survey and presentation of a great and rapidly advancing field of physico-chemical science."

The chapters are entitled: the surface tension of liquids; the surface tension of solutions; the surface films of insoluble materials; liquid-liquid interfaces; the gas-solid interface; the liquid-solid interface; differences of potential at interfaces; the conditions of stability in suspensions and emulsions; gels and hydrated colloids.

On p. 7 the author says that "for liquids which wet solids the contact angle is very nearly zero and may be taken as actually equal to zero without serious error." On p. 11 is the statement, that, in the work of Ramsay and Shields, "Ramsay did not make a sufficient allowance for the rise in the annular tube and in consequence all his values, and those of later workers who have adopted his figures for purposes of calibration for surface tensions are too low." The author does not agree with Morgan that Tate's laws hold for the falling-drop method. We are left rather up in the air as to whether one can or cannot determine molecular weights of liquids with any degree of accuracy from surface-tension measurements, pp. 25-30.

"We have noted that the Gibbs equation permits us to calculate the composition of the surface phase from a knowledge of the σ , N curve and the 'activity' of the solute in the solution; it does not however give us any information as to the thickness of the phase, beyond an indication that the liquid above the geometrical dividing surface is uniform in composition and does not acquire the characteristics of a phase in bulk. In the next chapter our attention will be devoted to the behaviour of films of insoluble substances on the surfaces of liquids and we shall have occasion to observe that we possess almost conclusive evidence that the surface phases of such films are but one molecule thick and further that the molecules of the insoluble material adsorbed on the liquid are oriented in a vertical plane; being attached to the liquid surface in the case of a complex molecule by some particular group or groups," p. 43.

When discussing the adsorption of vapors by mercury, p. 58, the author says: "It is further interesting to note that the transition from a primary adsorption film to a system in which the liquid is condensed on the mercury surface in the form of a thick layer, the free surface of which would possess the properties of the free surface of the liquid in bulk is not abrupt. We note that a point of instability is reached when the vapour pressure approaches saturation value and the apparent surface tension of the drop can fluctuate within relatively

wide limits. Iredale has shown that these values do not correspond to the tensions mercury/liquid, liquid/air, but are due to a condensed film, a secondary film on the mercury surface. Whilst the transition from the primary film to the thick layer through the formation of secondary layers takes place in this particular case within narrow limits of vapour pressure change, there is little doubt from the data that the change is definite, or that the secondary film must be built up from a great number of layers before we arrive at a film with the properties akin to those on the free surface of the liquid. This continuous change in the P, σ curves obtained by Iredale near the critical point P_{sat} appears to be similar in character to the changes, observed by Goard and Rideal, occurring in the activity, σ curves for phenol, water and salt mixtures near the salting-out point, and may be taken as evidence for a progressive thickening of the capillary layer before it acquires the properties of a bulk phase."

Under the spreading of liquids on liquids, pp. 60-86, the reviewer would have liked to have seen both a discussion and an explanation of what Gibbs has to say on this subject.

"We have noted that the adhesion of the polar groups to water and to one another is much greater than the weak adhesion of hydrocarbon chains either to water or to one another. It is thus reasonable to assume, an anticipation verified by Perrin, that soap films may be made up of composite surfaces each of which consists of two layers of oriented molecules of soap the outer surface of each side consisting of hydrocarbon chains and the polar groups held together with water as a sandwich between the oriented hydrocarbon chains. These elementary leaflets which will possess but little adhesion for one another may be built up to form thick films similar in structure to the crystalline fatty acids examined by Shearer. The leaflets may slip over one another with great ease, thus providing the play of interference colours noticed in soap films. The elementary leaflet has in fact been shown by Perrin and others to be two molecules in thickness," p. 91.

"The lubrication of metallic and other surfaces has been studied in detail by Hardy. Hardy has shown that surface spreading never occurs on solid surfaces and any spreading that does occur takes place through the vapour phase. Again, although the primary or unimolecular film is adsorbed extremely strongly to metallic surfaces when the substance contains a polar group such as the $-\text{COOH}$ or $-\text{OH}$, yet a secondary film consisting of a relatively thick multimolecular layer is generally built up. This secondary film takes a relatively long period of time to adjust itself and it appears probable that molecular orientation is proceeding in the layers of the oil at a rate much slower than for the underlying layer. On placing a load on a lubricated surface the load floats on the multimolecular layer which can be squeezed out by increasing the load until presumably a bimolecular layer with the molecules oriented towards the metal and load interface is left. The friction gradually rises as the multimolecular layer is squeezed out until it acquires a constant value dependent on the chemical constitution of the lubricant," p. 93.

The author comes out definitely in favor of the wedge theory of emulsifying agents, p. 113. "Thus the type of emulsion formed depends essentially on the relative cross-section of the non-polar and polar portions of the emulsifying agent." This statement will probably be eliminated in subsequent editions.

"A differentiation in the activities of surfaces may likewise be witnessed in a variety of chemical and catalytic processes. Thus we find that charcoal will undergo slow autoxidation when exposed to air; it will also catalytically accelerate the oxidation of a number of organic substances such as oxalic acid. By processes of selective poisoning of the charcoal it can be demonstrated quite readily that the portion of the surface which can accelerate the oxidation of oxalic acid is but a small portion of the surface which is available for say the adsorption of methylene blue and that but a minute fraction of the surface (less than 0.5% for a good sugar charcoal) is capable of undergoing autoxidation.

"Vavon and Husson have likewise clearly demonstrated the existence of patches of varying activity in platinum black showing that the progressive addition of a poison such as carbon disulphide will first inhibit the catalytic hydrogenation of substances more difficult to hydrogenate such as acetophenone without appreciably affecting the activity in respect to hydrogenation of nitrobenzene which is readily reduced," p. 143.

"The structural nature of adsorption compounds has likewise been demonstrated by Langmuir in his studies on the 'clean up' of electric lamps. Carbon monoxide was found to be strongly adsorbed at low temperature by tungsten and attempts to desorb the gas resulted in the fracture of the bonds holding the superficial tungsten atoms to the metal and the volatilisation of the whole group WCO. At higher temperatures however the W-CO union becomes weaker and the gas may be desorbed unchanged. Again he noted that small quantities of oxygen inhibit by selective adsorption the dissociation of hydrogen at the surface of a hot tungsten wire but the adsorbed oxygen is not as readily reduced as the oxide WO₃. In the case of oxygen adsorbed on charcoal the -C-O union appears to undergo a series of interesting changes. At very low temperatures according to Dewar a small fraction of oxygen may be adsorbed and desorbed from a charcoal surface, the union being apparently between the oxygen molecule and the charcoal and relatively feeble.

"At 0° to 100° C. part of the oxygen adsorbed on charcoal is endowed with catalytic properties, thus it will readily oxidise oxalic acid, amino acids, cystein and other similar compounds, whilst we would anticipate similar reactions if the oxygen molecule were now adsorbed in such a way as to cause a breakage of one of the two bonds $O=O \rightarrow O-O$.

At high temperatures, as is well known, oxygen is irreversibly adsorbed by charcoal and is only desorbed in the form of the gaseous oxides of carbon. The oxygen-carbon union now exceeds in strength the union between the superficial carbon and the underlying atoms," p. 153.

It is a question whether much value is to be ascribed to Paneth's determinations of the surface of charcoal, p. 173, until we know whether the maximum adsorption of methylene blue does or does not vary with the apparent pH.

"In accordance with theoretical expectations only strongly ionising solvents exhibit marked endosmose, e. g. chloroform and benzene are practically inert whilst nitrobenzene, the alcohols and water exhibit the phenomenon to a marked extent. Of the ions adsorbed by materials constituting the diaphragms, as in the case of direct adsorption, the hydrogen and hydroxyl ions have the greatest influence. In acid solutions most diaphragm materials acquire a positive charge relative to the liquid which moves to the anode, in alkaline solutions hydroxyl ions are adsorbed and the liquid moves to the cathode being positive relative to the negatively charged diaphragm," p. 225.

The author accepts Loeb's views as to the formation of sodium gelatinate and gelatine chloride, p. 316. It is interesting to note, p. 320, that "the studies of Pauli and his co-workers, however, have revealed the fact that isohydric solutions of different acids do not effect equal combination with the isoelectric protein; relatively more acetic acid for example being combined than hydrochloric acid in isohydric solutions. Again, both the actual position of these maxima as well as the magnitudes of the viscosities observed vary much with the nature of the acid employed. Thus the relatively weak oxalic acid appears to be a much stronger acid than sulphuric acid, whilst trichloroacetic acid does not differ appreciably from acetic acid in its effect on the viscosity of albumin. It is probable that the degree of solvation of the protein molecules and of the protein salts must not be regarded as constant but that they vary both with the nature of the salt and in the presence of neutral salts which exert like alcohol a desolvating action more or less complete on the solvated isoelectric protein as well as on the undissociated protein salts."

"The abnormality of the sodium soaps of the fatty acids of high molecular weight to form complexes in solution consisting of neutral colloid soap particles and of ionic micelle is to be attributed to the action of the long hydrocarbon chains, which are in themselves insoluble in water and tend to adhere to one another as the experiments of Langmuir have indicated. The detergent action and emulsifying power of soaps is likewise due to this cause. If we insert in an organic material containing hydrocarbon chains sufficiently long so as to render their mutual lateral adherence great enough to overcome in part the disintegration due to the thermal agitation, polar groups of the type -COOX, -SO₃X, -N(CH₃)₂I, which are sufficiently strong to immerse the hydrocarbon chains, in water, we obtain substances possessing colloidal nature; detergent action, emulsifying powers, gel and curd form-

ing properties will naturally be obtained. Such solutions, if the nonpolar portion of the molecule be too short or if too many polar groups be inserted or again if the polar medium water be replaced by one somewhat less polar such as alcohol, will no longer possess colloidal properties but will behave as true solutions."

Wilder D. Bancroft

Thermodynamics for Students of Chemistry. By C. N. Hinshelwood. 19 × 13 cm; pp. v + 196. New York: E. P. Dutton and Company, 1926. Price: \$1.80. "The book has been developed from lectures in which I have done what I can to make the fundamental ideas of thermodynamics as clear as possible, and particularly to explain the methods by which the abstract general laws are brought to bear upon the actual problems of physics and chemistry. By the degree in which this one object is attained the book must be adjudged successful or otherwise. It seeks to contribute something to the clearing up of those difficulties in understanding the principles of an unfamiliar subject which most students of chemistry experience; and I have tried throughout to discuss in some detail precisely those points which I know to be found difficult.

"There is no advantage in presenting a formally unified system, because the laws of thermodynamics can be clothed in many forms, choice between which is entirely a matter of individual preference or of circumstances, and nobody can be at home with original literature without some acquaintance with them all. I have tried, therefore, to exemplify a number of the more important methods.

"A good deal of stress is laid, all through the book, on the interconnection between the laws of thermodynamics and the kinetic theory. This is in a sense a departure from a rigid thermodynamic method, but I think the gain in clearness is very great. I am out of sympathy with those who regard thermodynamics as a science based upon empirical laws independent of the actual nature of things. If it were not for the molecular-kinetic nature of things there is no particular reason for believing that the laws of thermodynamics would be what they are."

The chapters are entitled: introductory; applications of the first law of thermodynamics; the second law of thermodynamics and Carnot's theorem; the Gibbs-Helmholtz equation, maximum work and free energy; applications of the isothermal reversible cycle; entropy and thermodynamic functions—conditions of equilibrium; the foundations of the phase rule; the problem of chemical combination; entropy and probability.

It is an excellent thing to have a book on thermodynamics in which the illustrations are selected with reference to the needs of the chemists. There are a number of very interesting things in this book.

In one of its several forms the second law of thermodynamics states that "it is impossible to derive a continuous supply of work by utilizing the heat of bodies at uniform temperature, these bodies remaining otherwise unchanged.

"The preceding argument might seem at first to imply that heat cannot be converted into work at all. Reflection shows that this is not a just implication. If we have a gas confined in a non-conducting cylinder by a piston, and if the pressure of the gas is greater than the external pressure, then those molecules of the gas which happen to be moving in the right direction may communicate some of their kinetic energy to the piston and enable it to move outward against the external pressure, thereby doing work. The gas molecules having lost kinetic energy, the gas is cooled. Work has therefore been done at the expense of the heat of the gas. But the essential point to notice is that the gas is changed not only in respect of having lost heat, but also in that it now occupies a larger volume. The case is fundamentally different from that of a gas, some of whose molecular kinetic energy is converted into mass kinetic energy of the whole gas, the volume remaining unchanged. Heat has been converted into work, but something else has happened as well. This is what we always find: there are many different devices for the conversion of heat into work, but, whatever the nature of the device may be, we always find, as a consequence of the nature of heat, that something besides the conversion must happen simultaneously; or, in thermodynamical

language, there must be 'compensation.' In the example just given this compensation consisted in the change of volume of a gas, i. e. the movement of the molecules further apart," p. 15

"Velocities are, in a sense, things just as definite as grains of sand, and, just as it is highly improbable that a bushel of red sand and a bushel of white sand once mixed will ever become separated again by stirring, so it is equally improbable that the molecular velocities will ever divide themselves spontaneously into two groups again. The temperature having become equalised will remain equal. The passage of heat from a colder to a hotter body means that the cold body would get still colder and the hot body still hotter, which is exactly the same thing as the reversal of a previous partial equalisation of temperature. The Second Law states that this does not occur, and is thus simply asserting a necessary consequence of the molecular nature of matter and the kinetic nature of heat.

"It will be seen that the second law of thermodynamics is not absolute. There is nothing mechanically impossible in the sort of process which it rules out. The direction of motion of individual molecules changes continually in a way which, regarding large numbers of them together, we can only describe as random. It may so happen that at one instant all the molecules of a body chance to be moving in the same direction—or, what is quite sufficient, to have a common component in one direction. The body then moves off as a whole. Indeed, it is probable that if we only wait long enough something of the sort will happen. The waters of the Red Sea could have divided from natural causes; the Pyramids might have reared themselves or the Andes might have risen from the plains at the expense of molecular energy. But the extreme improbability of any of these occurrences is realised when the number of molecules in a gram molecule is known to be 6.1×10^{23} . If we reflect on the number of unsuccessful trials which would accompany one successful attempt to sort by shuffling the fifty-two cards of a pack, no surprise is felt that the second law of thermodynamics is true in practice. Calculation shows that a lead weight is not likely once in geological ages to rise a millimetre from the ground.

"But the validity of the second law depends entirely upon the smallness of molecules, and the vastness of the numbers contained in all ordinary bodies. For systems composed of limited numbers of molecules, such as small colloidal particles, the deviations from the law cease to be inappreciable. The Brownian motion is a manifestation of the transformation of molecular motion into the mass motion of a particle, and a violation of the second law. The smaller the particle the greater the motion. There is no sharp line between small colloidal particles and complex molecules. The Brownian movement is at the same time mass motion and molecular motion," p. 17.

"The quantity A , the external work performed when any physical or chemical process is carried out reversibly at constant temperature, is of great importance. As we have seen, it can often be expressed as the sum of two terms one representing the work of expansion, the second work done in other ways. If the volume of the system is unchanged at the end of the process, then the quantity A is represented by the second term only. A is called the decrease in *free energy* of the system. The system, having done work A , is thought of as being, by that much, less endowed with this property called free energy. There is a slight confusion about the use of this term as it is sometimes applied rather to the total work less the work of expansion. All that matters, however, is to be clear about the facts. We shall use the term in the sense in which it was originally introduced, namely, the maximum work at constant temperature," p. 55.

"Every process which can be devised must have the same value of A . This fact renders the value of A independent of the specific mechanism of the device, and incidentally justifies the employment of A as a measure of the difference between two states of a system.

"We may state the result in the form that the net work done in an isothermal reversible cycle is zero. This is a principle of great importance in thermodynamical calculations. It is necessary to guard against the error of supposing it to be a consequence of the conservation of energy in any way. It is a direct consequence of the second law. The first would not contradict the possibility that work might have been done at the expense of heat absorbed," p. 67.

"Van't Hoff showed how the tendency of a solute to diffuse could be made the basis of a thermodynamical theory of solutions. The free energy changes accompanying the dilution of a solution are calculated in terms of the osmotic pressure.

"We shall follow van't Hoff's method, despite the objection which has sometimes been raised that the osmotic pressure is not a property of fundamental importance. This objection seems to be without any validity at all. The second law of thermodynamics can be regarded as a direct consequence of the molecular-kinetic nature of matter. This molecular-kinetic nature shows itself in its most primitive form in the tendency of a solute to diffuse in solution. The osmotic pressure is the direct measure of this tendency. Thus, from the theoretical point of view, the osmotic pressure is the most fundamental property of the solution. That its practical measurement is difficult is irrelevant. Thermodynamics introduces it only in the intermediate stages of the derivations; it does not necessarily enter into the final results," p. 78.

On p. 81 the author deduces the formula $\pi M_0 = 1000\rho RT \log(p/p_0)$ where π is the osmotic pressure, M_0 the molecular weight of the solvent as vapor, p , the vapor pressure of the pure solvent, and ρ the density of the solvent in grams per cubic centimeter. "This relation between the osmotic pressure of the solution and the vapour pressures of solvent and solution holds good only when the vapour of the solvent behaves in accordance with Boyle's law. When the vapour pressure is not very large, this assumption is not far from the truth. M_0 , it should be remembered, is the molecular weight of the solvent in the vapour state. This is important because the molecular weight in the vapour state usually has the simple value indicated by the chemical formula, while the actual molecular complexity of the solvent in the liquid state is often a matter of considerable doubt."

On p. 87 the author states that $(P_0 - P)/P_0 = n/N$ is "the form in which Raoult empirically established the law of vapour pressure lowering in dilute solutions." This is not the form that Hildebrand uses.

"The following difficulty is sometimes felt, and is only mentioned here because, remarkably enough, it is not confined to elementary students. If an applied hydrostatic pressure can prevent the entry of solvent, why cannot the bombardment pressure of the solute? Why in fact is the osmotic pressure not exerted the other way round? This difficulty depends of course upon a complete misunderstanding of the kinetic nature of pressure, and the explanation is simple. The difference between the bombardment pressures of the solvent on the two sides of the membrane measures its tendency to flow through, because the bombardment pressure on a given side of the membrane is proportional to the number of molecules which strike it, and therefore in turn to the number which pass through. If there is any difference on the two sides it means actually that more molecules of solvent are streaming one way than the other way. This, of course, cannot be balanced by the independent collisions of a foreign substance, the solute, on the membrane. On the other hand a hydrostatic pressure, whether exerted by a piston or by gravity, is transmitted by collisions through the solvent itself, and thus increases the actual solvent bombardment on the membrane until it is equal to the bombardment on the pure solvent side. (Incidentally the solute bombardment is also increased; by entering into refinements in the thermodynamics of osmotic pressure it may indeed be shown that the osmotic pressure is in fact slightly influenced by the total hydrostatic pressure.) There is now osmotic equilibrium; but the membrane is now no longer in hydrostatic equilibrium, and unless rigidly supported would move through the liquid. The whole matter becomes clear when it is once realised that osmotic equilibrium and hydrostatic equilibrium are not consistent with one another," p. 96.

"The phase rule does not say *which* phase disappears when the temperature of a non-variant system is changed. Supposing the temperature to rise slightly above the melting point, molecules begin to leave the surface of the solid more rapidly than they return. Now, the all-important thing from the point of view of the present argument is that the liquid is quite unaltered by a fresh influx of molecules of the same species as those of which it is already composed. Hence the rate at which it yields molecules to the solid is unaltered. The increased rate of dissolution of the solid leads to no change in the liquid whereby the opposing

rate of solidification can be increased. There is no reaction whatever to the increased rate of melting relative to the rate of solidification. Hence the change proceeds without check until the solid has completely melted. In a precisely analogous way, in any one-component two-phase system at constant pressure, a displacement of the temperature from the equilibrium value causes the velocity of transition of one phase into the other to become greater or less than the reverse change. The system being of one component and the pressure being constant, no concentration changes can come into play by way of counterbalancing this. Hence the system must change until one or the other of the phases has disappeared entirely. Other examples similar to the case of melting just described can easily be thought out, and the generality of this statement will then be clearly seen," p. 148.

"There is no sort of correlation between affinity and reactivity; it might be thought that, in general, substances with a large affinity for one another would combine more rapidly than those with little affinity, but the cursory consideration of a few cases like that of oxygen and hydrogen at ordinary temperatures soon shows that no such relation exists. The reverse is indeed very often true. It has been shown that, in the reaction $4\text{H} \rightleftharpoons \text{He}$, which according to our views of atomic structure is theoretically possible, the formation of helium at equilibrium should be almost complete and that the affinity should be much greater than in any of the more ordinary chemical reactions. Yet the velocity is so small that no trace of such helium synthesis has ever been detected. This extreme instance may help to emphasise the complete lack of correlation between reactivity and affinity. Usually, however, the equilibrium point can be reached by suitable means. Therefore the discussion of equilibrium relations without reference to reactivity is quite as important as that of reaction velocity. From the practical point of view both aspects of the subject naturally have to be considered," p. 154.

The reviewer does not feel absolutely certain that "the recent work of Perrin on colloidal solutions has placed the question of the real existence of molecules beyond dispute," p. 2. In colloidal solutions we are dealing with particles and one can admit the real existence of particles without necessarily committing oneself as to molecules.

On p. 11 the author says that "temperature itself has no meaning except in its application to a system consisting of many molecules. A single molecule has no temperature." It would be just as legitimate to say that a single molecule has the temperature corresponding to its speed at any moment.

On p. 51 and elsewhere the author speaks of the Gibbs-Helmholtz equation. So far as the reviewer knows, this is an equation which Helmholtz did deduce and which Gibbs could have, and perhaps should have, deduced but did not. The error goes back to Ostwald who was advertizing Gibbs at that time.

Wilder D. Bancroft

The Problem of Physico-Chemical Periodicity. By E. S. Hedges and J. E. Myers. Foreword by F. G. Donnan. 22 × 14 cm; pp. 95. London: Edward Arnold and Co., 1926. Price: 7 shillings, 6 pence. In most branches of science, phenomena of a periodic or rhythmic character are of fundamental importance. In chemistry, however, unless we regard the periodic classification of the elements as coming within this category, manifestations of periodicity have usually been regarded hitherto as being of minor significance and of little theoretical interest. In the present volume the authors have attempted to collect information concerning all cases of physico-chemical periodicity which have been reported and to present it in an organised form. They have been very successful. The scope of the subject turns out to be much wider than would have been suspected and a survey of it suggests that periodicity is a property which must be reckoned with in the development of many aspects of chemical theory.

Following a brief introduction, a chapter headed 'Static Periodicity' deals with phenomena which are periodic in respect of some quantity other than time or distance and includes references to periodic changes in the properties of metals during cold-working and to the work of Holker on the periodic opacity produced in colloidal systems by adding increasing quantities of electrolyte. Under the title of 'Periodic Structures' are described

examples of the Liesegang Phenomenon, of banded structures produced in the absence of chemical reaction, of similar structures obtained in the absence of a colloidal medium and of the rhythmic crystallisation of pure substances. The theories which have been advanced to account for these various structures are discussed. Later chapters deal with processes commonly known as 'periodic reactions.' The periodic dissolution of metals, the catalytic decomposition of hydrogen peroxide and the various electrochemical periodic processes form the substance of separate chapters, which contain a valuable summary of the literature, concluding with an account of the recent investigations which the authors themselves have carried out on these processes. Examples of reaction velocity-time curves are included in the text. Among 'miscellaneous reactions' are described the periodic luminosity of phosphorus, cases of periodicity in homogeneous systems, periodic enzyme action and periodic phenomena in the absorption of gases. The book concludes with a consideration of the conditions which appear to determine the occurrence of physico-chemical periodicity in general and a theory is suggested in which these various periodic phenomena are attributed to the presence of metastable surfaces: at such surfaces it is possible that surface tension becomes a periodic function of concentration. Though this is rather vague, it suggested an interesting field for further investigation. Thus, the authors point out the possibility that catalysis may be periodic in character and that periodicity in biological processes may arise through a progressive increase in the concentration of some substance at an 'active surface' in the organism.

All references to original work are collected as a bibliography at the end of the book. This is certainly the most complete record of contributions to our knowledge of the subject. Two omissions may, however, be noticed, *viz.* the observations of Grube and Reuss on the periodic structure of copper electrodeposited from a solution containing gelatin and the work of duNoüy on the rhythmic crystallisation of sodium chloride from solutions containing colloids.

The book is well set up and the text appears to be free from printer's errors. There does not, however, seem to be any reason why the plate referring to p. 19 should face p. 30. The numerous curves are well reproduced.

H. J. T. Ellingham

The Evolution and Development of the Quantum Theory. By N. M. Bligh. 22 × 15 cm; pp. 112. London: Edward Arnold and Co., 1926. Price: 9 shillings. Mr. Bligh tells the story of the development of the quantum theory in simple and clear language. In the modest dimension of a hundred pages, he introduces the reader to the ramifications of the theory and its applications to physics and chemistry. He follows in a historical sequence the development of the theory from Kirchhoff's law of cavity radiation and the empirical law of Stefan up to the modern theories of Bohr and Sommerfeld. The method of treatment is such that the reader with little mathematical knowledge can obtain a general idea of the whole field from the descriptive matter. It is not however a popular treatment of the subject in the true sense of the word, for the mathematical basis is given in some detail and is interspersed with references to the literature of the subject.

Books hitherto published on the quantum theory in the English language do not cover such a wide scope as the present volume; they are limited mainly to the modern theories of spectra, and refer but briefly to the laws of black body radiation. The first part of the present volume deals almost entirely with black body radiation including chapters on the early work, Wien's law, the Rayleigh-Jeans law, and Planck's law of radiation, and also contains an elementary introduction to statistical mechanics. In the second part, the author summarises the work on Einstein's law of photochemical equivalence, atomic heats, Planck's second quantum hypothesis, the quantum theory of optical spectra, and the correspondence principle. There was urgent need for a book of its scope which would provide a connected account of the theory without entering into too great detail. It is especially welcome to the physical chemist in whose sphere the quantum theory is destined to play an ever increasing rôle. The subject matter of the book forms a connecting link between physics and chemistry including as it does sections on photochemistry, the Nernst heat theorem, etc.

These sections, which deal with practical applications of the quantum theory to chemistry could have been extended with advantage.

The book, which is excellently printed on good paper, will form a convenient basis for any one wishing to become familiar with the elements of the subject and a convenient jumping off ground for the advanced textbooks and original literature to which references and bibliography are given.

W. E. Garner

An Introduction to Physical Chemistry. By F. B. Finter. 19×14 cm; pp. 276. London: Longmans, Green and Co., 1926. Price: 6 shillings. The teaching of physical chemistry in the upper classes of schools is a difficult matter. Whilst the subject is undoubtedly of sufficient importance in after life to justify the expenditure of a considerable amount of time at the universities and technical schools, it is frequently assumed that it is a matter too complex to be dealt with at all at schools. This is an error, as a glance at the curriculum in pure physics and in pure chemistry of any good school will indicate. Mr. Finter's book is valuable in that it supplies the type of material which might be well emphasised in education involving both physics and chemistry in the upper science classes. To the reviewer, whose only contact with school education is in the form of scholarship examinations, the book appears excellent as far as it goes; but several criticisms might be advanced. The author expressly excludes Werner's coordination hypothesis, the phase rule, surface tension, and the laws of thermodynamics. The doctrine of valency is of such a fundamental character that the simple ideas on pp. 17-20 might well be compressed and extended in scope. Again one finds in elementary classes at the University that the concepts of allotropy and phase change are most rapidly assimilated with the aid of phase rule diagrams, the shapes of the various lines being obtained from the Clapeyron-Clausius equation, with which the student is familiar in elementary physics. Finally surface energy as an introduction to colloids is of distinct value in that it robs colloids of the mysterious forces which are always conjured up to the mind of the tyro in this field. Whilst a case may be made for the exclusion of thermodynamics, there is little doubt that a reasonable fraction of an upper form can appreciate simple proofs founded on the cycle of Carnot and can make sufficient use of the calculus to reduce mathematical proofs to clear and concise statements; this fraction is worthy of encouragement even by footnotes or appendices. A few statements in the book might be questioned, thus in the law of Guldberg and Waage the rate of reaction is proportional to the active masses of the reactants. It would be better to make this statement and subsequently define active masses for gases, weak and strong solutions and solids rather than state this law in terms of molecular concentrations which statement is only true under certain conditions.

The insertion of questions and lecture experiments at the end of each section is a thoughtful and valuable addition to the volume.

Eric K. Rideal

Gmelins Handbuch der anorganischen Chemie. Part V. Edited by R. J. Meyer. Eighth edition. 26×18 cm; pp. xvi + 86. Leipzig and Berlin: Verlag Chemie, 1926. Price: 11 marks. This number on fluorine deals with the occurrence of fluorine or fluorides in nature, with the preparation and properties of the element, and with the compounds of fluorine. While no definite statement can be made, it is believed that the free fluorine found in some fluorspars by Moissan was produced by the action of radium radiation, though this has not been duplicated in the laboratory.

The reviewer was disappointed to find no references to the action of fluorine on solutions and no suggestion that this is an interesting subject.

Wilder D. Bancroft

THE AREA OF THE INTERNAL SURFACE OF CHARCOAL AS DETERMINED BY THE ADSORPTION OF THE NORMAL ALIPHATIC ALCOHOLS FROM AQUEOUS SOLUTION

BY W. E. GARNER, D. McKIE, AND B. C. J. G. KNIGHT

In the course of experiments on the adsorption of oxygen on a charcoal surface¹ it was found that carefully purified charcoal which had been previously heated to 950° under a high vacuum adsorbed small volumes of oxygen at room temperatures with the liberation of quantities of heat greater than those given by the same volume of oxygen on conversion to carbon monoxide. In an extension of this work it has been shown that each gram of charcoal is capable of adsorbing up to 0.4 cc.² of oxygen with the liberation of 68 Cal. for each gram mol. of oxygen adsorbed. After repeated treatment of charcoal with oxygen, and evacuation at 950°C, the charcoal always retains the power of adsorbing this volume of oxygen with the liberation of the same quantity of heat, even at end of thirty such experiments. The same behaviour was observed with another quite different sample of charcoal.

The heat of adsorption is so large that there can be but little doubt that this oxygen has reacted chemically with the surface carbon atoms, a conclusion which is in agreement with that of Rhead and Wheeler³.

It is a matter of some interest to determine whether this chemical change occurs over the whole of the carbon surface or is limited to certain suitably orientated carbon atoms⁴. A decision on this matter could be reached were it possible to determine the area of the charcoal used in the above experiments.

The methods which have been used hitherto for the determination of the area of porous bodies are usually based on measurements of the adsorption isotherms of substances from aqueous solution. The assumption is made that adsorption ceases with the completion of the monomolecular layer, and from the number of molecules adsorbed by unit weight of adsorbent and the approximate dimensions of an adsorbed molecule a deduction is made as to the area of the surface. This method has been tested in several cases on known areas of adsorbent and found to give results which are substantially correct.⁵ Paneth and Radu⁶ have applied the method to the charcoal surface, and deduce areas per gram for a sample of wood charcoal which range from 46.2 to 268.0 m². for different adsorbates, e.g., methylene blue, acetone, lead nitrate, etc. The wide range of these values must in part be due to the employment of unsatisfactory adsorbates. Very little attention has been paid to the nature of the adsorbed substance in these and similar investigations.

¹ Blench and Garner: *J. Chem. Soc.*, **125**, 1288 (1924).

² Further volumes are adsorbed but with the liberation of much smaller quantities of heat.

³ *J. Chem. Soc.*, **103**, 461 (1913).

⁵ Euler: *Z. Elektrochemie*, **28**, 446 (1922); van der Grinten: *J. Chim. phys.*, **23**, 209 (1926).

⁶ *Ber.*, **57**, 221, (1924).

In the light of recent investigations on monomolecular films, it is possible to indicate the criteria which should govern the choice of adsorbates in measurements of the areas of porous bodies. These are, (1) the longest molecular dimension should be less than half the diameter of the smallest capillary passages in the porous body into which the adsorbate can penetrate, (2) the molecules should be capable of packing easily on the surface and in such a manner that the lateral forces between the adsorbed molecules increase the

FIG. 1
I n-Propyl Alcohol
II n-Butyl Alcohol
III sec. Amyl Alcohol

stability of the film, and (3) the adsorbed molecules should be so orientated on the surface that the exposed groups of the molecules in the first layer exert weak subsidiary valency forces on the second layer; under these circumstances the tendency for the formation of the second layer will be very small.

With such adsorbates, a marked change in the character of an adsorbed film would be expected at that concentration at which the monomolecular layer is just completed. For example, the completion of the monomolecular layer should be indicated on the adsorption isotherm.

In the present investigation, the adsorption isotherms of a number of alcohols on charcoal have been investigated. These substances promised to fulfil most closely the conditions set out above. As was anticipated, a marked change in slope has been obtained at a point in the process of adsorption which very probably corresponds with the completion of the monomolecular film, (Fig 1). The curves also show evidence of the building up of a second layer which is held much less firmly than the first.

The method suggested by Donnan and Barker¹ was adopted in the determination of the adsorption isotherms. The surface tension-concentration curves of aqueous solutions of the alcohols were measured by the Jaeger bubbling method as modified by Sugden², over a range of concentrations from

¹ Proc. Roy. Soc., **85A**, 557 (1911).

² J. Chem. Soc., **125**, 27 (1924).

0.001 to 0.4% by weight of alcohol. From these curves and measurements of the surface tension of aqueous solutions of the alcohols when in equilibrium with charcoal, the equilibrium concentrations of the alcohol were calculated.

No difficulty was experienced in obtaining consistent values for the surface tension of aqueous solutions of the alcohols below heptyl by the above dynamical method. In the case of heptyl alcohol however, the freshly formed surface does not reach its equilibrium value in the time taken for the formation of the bubble. Frumkin¹ has noted a similar behaviour in the case of solutions of the fatty acids when using Wilhelmy's method. He finds that while the surface tension of caprylic acid reached its equilibrium value at once, capric acid solutions showed a time lag of 15 minutes, and lauric acid solutions a lag of more than one hour.

It is uncertain however whether Sugden's method gives equilibrium values for the surface tension of aqueous solutions of the lower members of the alcohols. Morgan and Neidle² obtained lower values for the surface tension of iso-amyl alcohol by the drop-weight method than we find for the same concentration of secondary amyl using Sugden's method. The cause of this discrepancy is not clear but it is of small moment as far as the employment of the method for analytical purposes is concerned, since it gives reproducible experimental results.

The definite change in the slope of the adsorption isotherms of n-propyl, n-butyl, and secondary amyl alcohol, occur at 0.00052, 0.00055, and 0.00038 gm. mols. of alcohol per gram of charcoal. The break occurs at the same value for the normal alcohols but at a lower value for the secondary alcohol. The equilibrium concentration remains constant throughout the initial portions of the curves for butyl and amyl alcohols, Fig. 1.

The occurrence of adsorption in steps might be interpreted as due to the presence of capillaries in the charcoal possessing diameters varying in steps. The main objection to this view is that it affords no satisfactory explanation of the constancy of the equilibrium concentrations during the initial stages of the adsorption. To explain this in a satisfactory manner, it would be necessary for the capillary passages not only to change discontinuously from small to large diameters, but also that the smaller capillaries must be of uniform diameter throughout their length. This is very unlikely especially in a charcoal which has been subjected to the erosive action of oxygen at high temperatures.

On the other hand, the results are in complete harmony with the view that the change of slope of the adsorption corresponds with the completion of a monomolecular film on the surface of the charcoal. On this theory, the number of gm. mols. composing the completed monomolecular film should depend upon the cross section of the molecules of adsorbate. This number should be greater for the primary than for the secondary alcohols, since the former have the smaller cross section. This is found to be the case.

¹ Z. physik. Chem., 116, 481 (1925).

² J. Am. Chem. Soc., 35, 1860 (1913).

The adsorption isotherms resemble the surface tension area curves obtained by Adam and Jessop¹ for monomolecular films of straight chain acids on water and it is probable that the horizontal portions of both sets of curves owe their existence to phenomena analogous to those occurring in certain two-component systems e.g. CaO-CaCO_3 .

The constancy of the dissociation pressure of CaO-CaCO_3 systems at constant temperature was explained by Langmuir as due to the fact that the condensation of carbon dioxide molecules on the surface and their evaporation from the surface took place at the edges of islands of CaCO_3 . A molecule of carbon dioxide on colliding with a molecule of CaO only underwent reaction when the molecule of CaO was adjacent to one of CaCO_3 . Similarly, carbon dioxide could only evaporate from molecules of CaCO_3 when these were adjacent to CaO . On the basis of this mechanism it was shown that the dissociation pressure should be constant as long as both CaO and CaCO_3 are present. It would thus appear that the lateral forces between the carbon dioxide and the calcium carbonate molecules on the surface play an important role in determining the stability of calcium carbonate.

In adsorbed films of straight chain compounds, the lateral forces are of considerable magnitude. The molecules will tend to group themselves in 'islands' over the surface; isolated molecules being held less firmly by the surface will possess a greater solution pressure than molecules grouped together. It follows therefore that adsorption of molecules of straight chain compounds will occur most frequently on areas adjacent to those on which molecules are already adsorbed, i.e. the adsorption will be analogous to the condensation of carbon dioxide on the system, CaO-CaCO_3 . Such a mechanism would certainly account for the constancy of the equilibrium concentration during the building up of the monomolecular layer of amyl and butyl alcohol, and also for the curved isotherm of propyl alcohol over this region, for in the case of the latter, where the lateral forces are smaller in magnitude, isolated molecules would be expected to occur more frequently on the surface. The structure of an incomplete monomolecular layer of propyl alcohol will approach that of the surface of the system, $\text{Fe}_3\text{O}_4\text{-Fe}_2\text{O}_3$, which does not give a constant dissociation pressure.

From the number of molecules of alcohol adsorbed at the change of slope of the adsorption isotherm, and assuming that the cross sectional area per alcohol molecule is 20.5 sq. A. U., the value found by Adams for thin films on water, the internal area of unit weight of charcoal is found to be 66 m². Taking the density of charcoal² as 1.9, it can be shown that the carbon surface is composed of approximately 1.4×10^{21} carbon atoms. The total number of carbon atoms per gm. is 5.05×10^{22} , so that the ratio of surface to total atoms is 1:36. The 'active' atoms per gm. of charcoal number 1.0×10^{19} , assuming that each oxygen molecule is held by one active atom. The ratio of 'active' atoms to the total carbon atoms is 1:5000, or one in 140 of the carbon atoms on the surface combine with oxygen to give a heat of adsorption of 68 Cal/gm. mol.

¹ Proc. Roy. Soc., 110A, 423-441 (1926).

² Cude and Hulett: J. Am. Chem. Soc., 42, 391 (1920).

It is possible that oxygen molecules will penetrate pores in the charcoal which will not admit the molecules of alcohol, in which case some of the active carbon atoms may be situated on areas not measured by the above method. This will not, however, affect the main conclusion of this paper.

This investigation thus provides very definite evidence that a small fraction of the atoms composing the internal surface of charcoal are in a highly activated state. This confirms the views of Rideal and Wright (*loc. cit.*) which were based on investigation of oxidation processes occurring on the charcoal surface.

No two atoms on an amorphous surface will be exactly alike as regards position or energy content; their surface energies will vary continuously from a very large value down to zero accordingly to some probability law. It is thus necessary to define precisely the lower limit for the energy of the 'active' atom. This we have done arbitrarily above in defining the 'active' carbon atoms as those which give a mean value for the heat of adsorption of oxygen of 68 Cal.

Experimental

The charcoal was that employed previously in the determinations of heats of adsorption of oxygen. It contained 0.2% of ash (chiefly silica).

The n-propyl and n-butyl alcohols were Kahlbaum preparations. They were dried over potassium carbonate and distilled, the middle constant-boiling fraction being used in the adsorption experiments. B. Pts: n-propyl alcohol, 97.5°; n-butyl alcohol 117.5° (754 mm.); secondary amyl alcohol, 127-128°; n-heptyl alcohol (Eastman Kodak Co.), 174.5° (753.5 m.m.).

Conductivity water from a metal still was found to give low values for the surface tension. It was redistilled in glass with alkaline permanganate. The capacity of the still was 2 litres. The first and last 500 cc. were rejected and the middle fraction collected in a quartz flask. This was distilled in an all quartz apparatus and stored in a stoppered quartz flask. It gave a surface tension of 72.2 dynes/cm. at 25°C. (Harkins: 72.02 dynes/cm; Bircumshaw: 72.2 dynes/cm. at 25°).

Adsorption Isotherms. 0.5 grain of alcohol was weighed into each of twelve stoppered hard glass tubes of about 75 cc capacity, which had been previously treated with hot chromic-sulphuric acid mixture, washed with the above distilled water and dried. 25 cc. of the alcoholic solutions were added to the tubes. These solutions were made up in the tubes by weighing the amounts of the specially purified water and of a standard solution of the alcohol added. The standard alcohol solutions were prepared by weighing the dry alcohol and adding water to give a convenient concentration.

The tubes containing the alcoholic solutions and charcoal were suspended in a thermostat at 25° for six days, with occasional shaking. The concentration of the solutions was found to change slowly up to the 4th day. Attempts were made to hasten the attainment of equilibrium by shaking the tubes in an air thermostat, but this had no effect on the rate of adsorption and this procedure was omitted in the later determinations.

After equilibrium had been reached, the surface tension of the solutions was determined by the Jaeger method. The bubbler devised by Sugden¹ was employed. Several capillaries were used, the instrument being calibrated each time with dry thiophene-free benzene ($\sigma = 28.23$ dynes/cm.). Great care was exercised in cleaning the bubbler and capillary. A trace of grease from the finger on the capillary invariably spoiled it by causing sticking. Hot chromic-sulphuric acid was used for cleaning; it was found better to dilute slightly the concentrated sulphuric acid.

The pressure differences for bubbling from the wide tube or from the capillary were read on an alcohol gauge by means of a cathetometer. The gauge was water jacketed, and a graph was prepared by plotting density $\times g$ against temperature. The rate of bubbling was one bubble per second, and the bubbling was not continued for any length of time to avoid loss of alcohol carried away by the air current. Three successive readings of pressure gave concordant values. Concordant values could not however be obtained for heptyl alcoholic solutions above 0.0182% by weight. Except in this case, the value for the surface tension was independent of the rate of bubbling.

The results for the surface tensions of alcoholic solutions at a number of concentrations are given in Table I.

The slight lowering of the surface tension in the initial portions of the isotherms is not due to the abstraction of substances from the charcoal or from the glass of the containing vessel, as shown by blank experiments in which no alcohol was present. There is thus a small concentration of alcohol in equilibrium with the charcoal over this range. It is however too small to be measured accurately by the method employed.

One of the authors (D. McKie) wishes to express his thanks to the Department of Scientific and Industrial Research for a maintenance grant which has enabled him to carry out part of this work.

STUDIES IN ADSORPTION. XVIII

Coagulation of Sols by a Mixture of Electrolytes and the Phenomena of Positive and Negative Acclimatization

BY S. GHOSH AND N. R. DHAR

In the foregoing papers of this series¹ we have shown that the phenomenon of 'ionic antagonism', viz. that more of an electrolyte is necessary to coagulate a sol in presence of another electrolyte, is observable with a sol when coagulated by a mixture of electrolytes, one of which possesses an ion carrying the same charge as the sol and capable of being adsorbed by the sol. Thus we have shown that enough 'ionic antagonism' is observable when sols of prussian blue, arsenious sulphide, antimony sulphide, and mastic are coagulated by mixture of electrolytes like KCl and BaCl₂, KNO₃ and CaCl₂, because these sols are capable of adsorbing similarly charged ions like Cl⁻, NO₃⁻, etc. We have also shown that 'ionic antagonism' is not observed when sols of ferric hydroxide, chromium hydroxide, etc., are coagulated by mixtures like KCl and K₂SO₄, KCl and K₂C₂O₄, etc., simply because these sols do not appreciably adsorb similarly charged ions from KCl. On the other hand, we have shown that considerable 'ionic antagonism' exists when these hydroxide sols are coagulated by such mixtures of electrolytes as K₂SO₄ and Al(NO₃)₃, K₂SO₄ and FeCl₃, K₂SO₄ and HCl, etc., where the positively charged sol can markedly adsorb the similarly charged ions of Al⁺⁺⁺, Fe⁺⁺⁺, H⁺, etc.

In former papers we have pointed out that the abnormal behaviour of sols on dilution, viz. that more of an electrolyte is necessary to coagulate a dilute sol than a concentrated one, originates from the appreciable adsorption of similarly charged ions from the coagulating electrolytes. We have also proved that the phenomenon of acclimatization, viz. that more of an electrolyte is necessary to coagulate the sol when the addition is slow than when it is rapid, observed with some sols is also due to the adsorption of similarly charged ions from the added electrolytes. We were, therefore, led to believe that (1) abnormal dilution effect, (2) ionic antagonism, and (3) the phenomenon of acclimatization, are essentially connected and go hand in hand.

We have already reported our results on the influence of concentration of a sol on its coagulation with fifteen different sols by various electrolytes in the previous part of this series. We shall now present our results on the coagulation of some of these sols by a mixture of electrolytes. The phenomenon has also been studied for some sols and these are also recorded at their proper places.

Coagulation by mixtures of electrolytes. Ferric hydroxide sol:—

In a previous paper we have shown that well-marked 'ionic antagonism' is observed when a sol of ferric hydroxide (positive) is coagulated by such

¹ Ghosh and Dhar: J. Phys. Chem., 29, 435, 659 (1925).

mixtures as KCl and FeCl_3 , KCl and $\text{Al}(\text{NO}_3)_3$, K_2SO_4 and $\text{Al}(\text{NO}_3)_3$, etc. In this paper we have investigated the coagulation of the same sol with mixtures of HCl and KCl, HCl and K_2SO_4 , and HCl and $\text{K}_3\text{Fe}(\text{CN})_6$.

In Tables I-III the experimental results are given:—

TABLE I

Concentration of the sol = 1.43 gm. Fe_2O_3 per litre

Amount of sol taken each time = 2 c.c.

Volume = 6 c.c. Immediate turbidity is observed

HCl N/100 added in c.c.	KCl to coagulate in c.c.
0	0.95 of N/5
0.1	0.85 of N
0.3	1.55 "
0.5	1.85 "
0.7	1.95 "
0.9	1.95 "

TABLE II

Coagulation with K_2SO_4 in presence of HCl.

N/100 HCl added in c.c.	N/400 K_2SO_4 to coagulate in c.c.
0	0.65
0.2	0.95
0.5	1.05
0.7	1.10
0.9	1.10

TABLE III

Coagulation with $\text{K}_3\text{Fe}(\text{CN})_6$ in presence of HCl.

N/100 HCl added in c.c.	N/400 $\text{K}_3\text{Fe}(\text{CN})_6$ to coagulate in c.c.
0	0.70
0.2	1.95
0.4	2.00

The results given in Tables I-III prove that more marked stabilisation takes place when ferric hydroxide sol is coagulated by KCl than that observed when it is coagulated by K_2SO_4 and $\text{K}_3\text{Fe}(\text{CN})_6$ in presence of HCl. This is, because H_2SO_4 and $\text{H}_3\text{Fe}(\text{CN})_6$ being weaker acids than HCl, there is a diminution in H^+ ion concentration in the mixture of HCl and K_2SO_4 or HCl and $\text{K}_3\text{Fe}(\text{CN})_6$. Hence in presence of HCl the stabilization, which is a direct consequence of the adsorption of hydrogen ions, can not be developed so well when the sol is coagulated with K_2SO_4 or $\text{K}_3\text{Fe}(\text{CN})_6$ as that observed with KCl.

Aluminium hydroxide sol.

Coagulation of the same aluminium hydroxide sol as used in the dilution experiments has been effected by various pairs of electrolytes and the results are given in Tables IV-V.

TABLE IV

Concentration of the sol = 0.60 grm. Al_2O_3 per litre.

Amount of sol taken each time = 2 c.c.

Volume = 6 c.c. Time = 1 hour.

Coagulation of aluminium hydroxide sol with a mixture of KCl and K_2SO_4 .

N/10 KCl added in c.c.	N/400 K_2SO_4 for complete coagulation in c.c.			% Difference
	Observed	Calculated	Difference	
0	0.65	—	—	—
1.25	0	—	—	—
0.30	0.45	0.46	-0.01	- 2.2
0.60	0.30	0.33	-0.03	- 9.1
0.90	0.15	0.17	-0.02	-11.8

TABLE V

H/10 KCl added in c.c.	N/400 $\text{K}_2\text{C}_2\text{O}_4$ for complete coagulation in c.c.			% Difference
	Observed	Calculated	Difference	
0	1.25	—	—	—
1.25	0	—	—	—
0.3	0.85	0.95	-0.10	-10.5
0.6	0.65	0.60	+0.05	+ 8.3
0.9	0.40	0.35	+0.05	+14.3

The results in Tables IV-V show that when aluminium hydroxide sol is coagulated with mixtures of electrolytes like KCl and K_2SO_4 or KCl and $\text{K}_2\text{C}_2\text{O}_4$, practically additive amounts of K_2SO_4 or $\text{K}_2\text{C}_2\text{O}_4$ are required to coagulate the sol in presence of varying amounts of KCl. Aluminium hydroxide sol, therefore, behaves normally when coagulated by a mixture of electrolytes of varying valencies. We have already shown that aluminium hydroxide sol also behaves normally on dilution when coagulated by either univalent or bivalent or polyvalent coagulating ions.

In Tables VI-VII we shall give our results on the coagulation of aluminium hydroxide sol by KCl in presence of either HCl or $\text{Al}(\text{NO}_3)_3$:—

TABLE VI

Coagulation of aluminium hydroxide sol with KCl in presence of HCl.

N/500 HCl added in c.c.	Amount of KCl to coagulate in c.c
0	1.25 of N/10
0.1	0.25 of N
0.2	0.70 "
0.3	1.05 "
0.4	1.35 "

TABLE VII

Coagulation of aluminium hydroxide sol with KCl in presence of $\text{Al}(\text{NO}_3)_3$.

N/500 $\text{Al}(\text{NO}_3)_3$ added in c.c.	Amount of KCl to coagulate in c.c.
0	1.25 of N/10
0.1	0.30 of N
0.2	0.95 "
0.3	1.40 "
0.4	1.85 "

These results prove that the sol is markedly stabilised in presence of HCl and $\text{Al}(\text{NO}_3)_3$ and that far greater amounts of KCl are required to coagulate the sol than that required for coagulation when no HCl or $\text{Al}(\text{NO}_3)_3$ is present. These results are, therefore, in line with those obtained by us on the coagulation of ferric hydroxide sol by KCl in presence of HCl or $\text{Al}(\text{NO}_3)_3$ or FeCl_3 and show that like ferric hydroxide, aluminium hydroxide can appreciably adsorb positive ions like H^+ , Al^{+++} , Fe^{+++} , etc.

One remarkable fact is, however, obvious when our results on the coagulation of ferric hydroxide and aluminium hydroxide sols by KCl in presence of HCl are compared. The amount of KCl required to coagulate a sol of ferric hydroxide in presence of 0.1 c.c. N/100 HCl is about 4.47 times greater than that of KCl required to coagulate the sol when no acid is present. On the other hand, in the presence of 0.8 c.c. of N/500 HCl, the amount of KCl required to coagulate a sol of aluminium hydroxide is 10.8 times greater than that of KCl required to coagulate the same sol in the absence of the acid. In other words, HCl exerts a greater stabilising influence on aluminium hydroxide sol than on ferric hydroxide sol.

We have already reported that aluminium hydroxide sol could not be coagulated with either HCl or $\text{Al}(\text{NO}_3)_3$, because appreciable quantities of this sol dissolve in these electrolytes at their precipitating concentrations, whilst ferric hydroxide sol could be coagulated by these electrolytes. These results throw a considerable light on the stabilisation of these sols by the adsorption of a similarly charged ion and will be discussed in a separate paper on 'ageing of sols'.

Chromium hydroxide sol (positively charged).

Weiser and collaborators¹ have shown that chromium hydroxide sol behaves normally on dilution and that the sol shows the additive relationship when coagulated by a mixture of electrolytes like KCl and K_2SO_4 or KCl and $\text{K}_2\text{C}_2\text{O}_4$.

TABLE VIII

Coagulation of chromium hydroxide sol by NaCl in presence of HCl.

Concentration of the = 3.91 grms. Cr_2O_3 per litre.

Amount of sol taken each time = 4 c.c.

Total volume = 10 c.c.; Time = 1 hour.

Amount of N/100 HCl added in c.c.	Amount of N/100 NaCl to coagulate in c.c.
0	1.55
0.1	2.20
0.2	3.25
0.3	> 4.60

We have investigated the coagulation of this sol by electrolytes in presence of hydrochloric acid. The sol was prepared by adding ammonium hydroxide at the ordinary temperature to a solution of chromium chloride,

¹ J. Phys. Chem., 25, 655, 742 (1921); 28, 232, 1253 (1924).

till the precipitate of $\text{Cr}(\text{OH})_3$ just appeared. The sol thus prepared was first dialysed in the cold for a week and then hot dialysis was continued for another week. The sol was free from acid but on dissolving the sol with nitric acid, a precipitate was obtained with silver nitrate, showing that chloride ion was not completely removed even by hot dialysis. In Tables VIII-IX my results are given when this sol is coagulated by NaCl and K_2SO_4 in presence of HCl :—

TABLE IX
Coagulation by K_2SO_4 in presence of HCl .

Amount of N/100 HCl added in c.c.	Amount of N/500 K_2SO_4 to coagulate in c.c.
0	2.5
0.1	2.9
0.2	3.6
0.3	4.2

The foregoing results prove that like ferric hydroxide and aluminium hydroxide sols, chromium hydroxide sol is stabilised in presence of an acid like HCl , due to the preferential adsorption of similarly charged hydrogen ions. In this case the stabilisation is much less than that observed with ferric hydroxide and aluminium hydroxide sols.

Thorium hydroxide sol.

The results in Table X have been obtained when thorium hydroxide sol is coagulated by a mixture of electrolytes:—

TABLE X

Concentration of the sol = 1.36 grms. ThO_2 per litre.

2 c.c. of the sol are taken each time.

Volume = 6 c.c.; Time = 1 hour.

Coagulation of thorium hydroxide sol with a mixture of KBrO_3 and K_2SO_4 .

N/2.4 KBrO_3 added in c.c.	N/500 K_2SO_4 for complete coagulation		Difference	% Difference
	Observed	in c.c. Calculated		
0	2.40	—	—	—
2.60	0	—	—	—
0.4	1.80	2.03	-0.23	-10.3
0.8	1.55	1.66	-0.11	-6.6
1.2	1.20	1.30	-0.10	-7.7

These results show that additive relationships are observed when thorium hydroxide sol is coagulated with a mixture of KBrO_3 and K_2SO_4 . It has already been shown that thorium hydroxide sol behaves normally towards dilution when coagulated by either KBrO_3 or K_2SO_4 .

Manganese dioxide sol (negatively charged)

The results in Tables XI-XIV have been obtained when negatively charged manganese dioxide sol is coagulated by a pair of electrolytes:—

TABLE XI

Concentration of the sol = 0.80 gm. MnO_2 per litre.

Amount of sol taken each time = 2 c.c.

Volume = 8 c.c.; Time = 1 hour.

Coagulation of manganese dioxide sol with a mixture of KBr and BaCl_2 .

N/20 KCl added in c.c.	N/20 KBr for complete coagulation in c.c.		Difference	% Difference
	Observed	Calculated		
1.15	0	—	—	—
0	1.15	—	—	—
0.1	1.00	1.05	-0.05	-4.8
0.5	0.65	0.65	0	0
0.9	0.20	0.25	-0.05	-20

TABLE XIV

Coagulation of manganese dioxide sol with a mixture of KOH and KCl.

N/20 KOH added in c.c.	N/20 KCl for complete coagulation in c.c.		Difference	% Difference
	Observed	Calculated		
2.8	0	—	—	—
0	1.15	—	—	—
0.3	1.50	1.04	0.46	44.2
0.7	1.6	0.86	0.74	86.0
1.1	1.5	0.70	0.80	114.3
1.5	1.35	0.53	0.82	157.7
1.9	1.15	0.37	0.78	210.8
2.3	0.60	0.21	0.39	185.7

It will be seen from Tables XI-XIV that negatively charged manganese dioxide sol behaves normally when coagulated by mixtures of KBr and BaCl₂, KCl and BaCl₂, and MgCl₂ and BaCl₂, and, therefore, additive relationships are observed when the sol is coagulated by these mixtures of electrolytes. 'Ionic antagonism' is, however, observed when the sol is coagulated by a mixture of KOH and KCl. It has been shown that appreciable amounts of OH' ions are adsorbed by manganese dioxide sol. We have already proved that comparatively greater amounts of KOH are necessary to coagulate the sol than those of other univalent anions and that the sol has a tendency to behave abnormally on dilution when coagulated by KOH. This proves that 'ionic antagonism' or more of an electrolyte is necessary to coagulate the sol in presence of an another electrolyte and abnormal dilution effect are essentially connected and go hand in hand.

Manganese dioxide sol (positively charged).

It has already been shown that this sol behaves normally on dilution when coagulated by KCl, KNO₃, K₂SO₄ etc., whilst it behaves abnormally when coagulated by AgNO₃ and CuCl₂. I have indicated that this peculiar behaviour is due to the fact that manganese dioxide sol appreciably adsorbs both Ag' and Cu'' ions.

In Tables XV-XVII the results are given as obtained by me, when this sol is coagulated by a mixture of electrolytes:—

TABLE XV

Concentration of the sol = 0.92 grm. MnO₂ per litre.

Amount of sol taken each time = 2 c.c.

Volume = 8 c.c.; Time = 1 hour.

TABLE XVII

Coagulation with a mixture of AgNO_3 and KNO_3 .	
Amount of N/2.725 AgNO_3 added in c.c.	Amount of N/10 KNO_3 to coagulate in c.c.
0	0.8
0	0.8
1.2	0
0.1	0.95
0.2	1.10
0.3	1.25
0.4	1.10
0.5	0.90
0.6	0.75

An examination of Tables XV-XVII shows that marked 'ionic antagonism' is observed when the sol is coagulated with a mixture of either CuCl_2 and KNO_3 or AgNO_3 and KNO_3 , whilst additive relationships are obtained when the sol is coagulated by a mixture of KNO_3 and K_2SO_4 . These results confirm our view that 'ionic antagonism' is due to the adsorption of the similarly charged cations Ag^+ and Cu^{++} by the positively charged sol.

Vanadium pentoxide sol.

Influence of change of concentration of this sol on its coagulation has already been investigated and we have shown that this sol behaves normally towards dilution irrespective of the valency of the coagulating ion. In Table XVIII we give our results on the coagulation of this sol with a mixture of electrolytes:—

TABLE XVIII

Concentration of the sol = 0.92 gm. V_2O_5 per litre.

Amount of sol taken each time = 2 c.c.

Volume = 6 c.c.; Time = 1/2 hour.

Coagulation of vanadium pentoxide sol with a mixture of KCl and BaCl_2 .

N/10 KCl added in c.c.	N/500 BaCl_2 for complete coagulation in c.c.		Difference	% Difference
	Observed	Calculated		
0	1.00	—	—	—
0.8	0	—	—	—
0.1	0.65	0.875	-0.225	-25.7
0.3	0.40	0.625	-0.225	-36.0
0.5	0.30	0.375	-0.075	-20.0

The results in Table XVIII show that the sol requires slightly smaller amounts of BaCl_2 than the calculated amounts when it is coagulated with a mixture of KCl and BaCl_2 . These results, therefore, prove that the behaviour of this sol is normal when coagulated with a mixture of electrolytes of widely varying coagulating powers.

Stannic hydroxide sol (positively charged).

Coagulation of the same positively charged stannic hydroxide sol as used in dilution experiments has been determined by a pair of electrolytes and the following results have been obtained:—

TABLE XIX

Concentration of the sol = 3.52 grms. SnO_2 per litre.

Amount of sol taken each time = 2 c.c.

Volume = 10 c.c.; Time = 1 hour.

KCl N/500 added in c.c.	K ₂ SO ₄ N/4,000 to complete coagulation in c.c.			% Difference
	Observed	Calculated	Difference	
1.9	0	—	—	—
0	1.20	—	—	—
0.1	0.90	1.14	-0.24	-21.1
0.4	0.80	0.95	-0.15	-15.8
0.7	0.65	0.76	-0.11	-14.5
1.0	0.55	0.57	-0.02	-3.5

When positively charged stannic hydroxide sol is coagulated by a mixture of KCl and K₂SO₄ slightly smaller quantities of K₂SO₄ are required to coagulate the sol than the calculated amounts. In other words, this sol, which we have already proved to behave normally on dilution towards its coagulation by various electrolytes, also behaves normally when coagulated by a mixture of electrolytes of varying valencies.

Uranium ferrocyanide sol.

It has already been shown that this sol has a tendency to behave normally on dilution towards all electrolytes except with potassium ferrocyanide, because ferrocyanide ions are appreciably adsorbed by the sol.

In Tables XX-XXII the results are given when this sol is coagulated by a mixture of electrolytes:—

TABLE XX

Concentration of the sol = 2.09 grms. of uranium ferrocyanide per litre.

Amount of sol taken each time = 3 c.c.

Volume = 10 c.c.; Time = 2 hours.

Coagulation with a mixture of KCl and BaCl₂.

1.3	1.05	0.34	0.71	208.9

TABLE XXII

Coagulation with a mixture of $BaCl_2$ and $MgCl_2$.

$N/25$ $MgCl_2$ added in c.c.	$N/25$ $BaCl_2$ for complete coagulation in c.c.		%	
	Observed	Calculated	Difference	Difference
0	1.20	—	—	—
1.5	0	—	—	—
0.4	0.85	0.88	-0.03	-3.4
0.7	0.65	0.64	0.01	1.5
1.1	0.35	0.32	0.03	9.4

An examination of Tables XX-XXII shows that greater 'ionic antagonism' is observed when the sol is coagulated by a mixture of $K_4Fe(CN)_6$ and KCl than that observed when the sol is coagulated by a mixture of KCl and $BaCl_2$. This is because ferrocyanide ions highly stabilised uranium ferrocyanide sol due to the greater adsorption of this ion. A very interesting set of results is obtained when a dilute sol of uranium ferrocyanide is coagulated by a mixture of $K_4Fe(CN)_6$ and KCl, Table XXIII.

TABLE XXIII

Coagulation of a dilute sol with a mixture of $K_4Fe(CN)_6$ and KCl.

Amount of sol taken each time = 1 c.c.

Volume = 10 c.c.; Time = 2 hours.

$2N$ $K_4Fe(CN)_6$ added in c.c.	N KCl to complete coagulation in c.c.		%	
	Observed	Calculated	Difference	Difference
0	1.8	—	—	—
1.8	0	—	—	—
0.1	2.20	1.70	0.5	29.4
0.3	2.35	1.50	0.85	56.7
0.5	2.35	1.30	1.05	80.8
0.7	2.20	1.10	1.10	100.0
0.9	2.15	0.9	1.25	138.9
1.1	1.95	0.7	1.25	178.6
1.5	0.95	0.3	0.65	216.7
1.3	1.55	0.5	1.05	210.0

From our results on the coagulation of concentrated and diluted sols of uranium ferrocyanide with a mixture of $K_4Fe(CN)_6$ and KCl it is evident that 'ionic antagonism' is more marked in the case of the dilute sol than the concentrated one. This result is extremely important as it connects the dilution effect of a sol with the behaviour of the sol towards a mixture of electrolytes.

Gum dammar.

Coagulation of gum dammar sol with a pair of electrolytes has been studied and the results in Tables XXIV-XXV have been obtained.

TABLE XXIV

Concentration of the sol = 0.87 grm. dammarharz per litre.

Amount of sol taken each time = 2 c.c.

Volume = 10 c.c.; Time = 1 hour.

Coagulation of gum dammar sol with a mixture of KCl and $BaCl_2$.

N/2 KCl added in c.c.	N/10 $BaCl_2$ for complete coagulation			% Difference
	Observed	in c.c. Calculated	Difference	
0	1.30	—	—	—
2.60	0	—	—	—
0.20	1.40	1.20	0.20	16.7
0.60	1.30	1.00	0.30	30.0
1.00	1.15	0.80	0.35	43.8
1.40	1.00	0.60	0.40	66.7
1.80	0.70	0.40	0.30	75.0

TABLE XXV

Coagulation of gum dammar sol with a mixture of KNO_3 and $SrCl_2$.

N KNO_3 added in c.c.	N/10 $SrCl_2$ for complete coagulation			% Difference
	Observed	in c.c. Calculated	Difference	
0	1.30	—	—	—
1.20	0	—	—	—
0.10	1.40	1.19	0.21	17.6
0.30	1.30	0.98	0.32	32.6
0.50	1.15	0.76	0.39	51.3
0.70	0.90	0.54	0.36	66.7

The foregoing results show that when gum dammar sol is coagulated by mixtures of electrolytes like KCl and $BaCl_2$ or KNO_3 and $SrCl_2$ marked 'ionic antagonism' is observed. We have already shown that this sol requires greater quantities of an univalent and a bivalent cation to coagulate a dilute sol than a concentrated one.

It must be emphasised here that 'ionic antagonism' observed with a mixture of electrolytes like KCl and $BaCl_2$ with gum dammar sol is comparatively greater than that observed with mastic sol. This is because the coagulating power of $BaCl_2$ is twenty times greater than that for KCl with gum dammar sol, whilst it is only seven times greater than that for KCl with mastic sol.

Consequently, the adsorption of similarly charged Cl' ions by gum dammar sol is more prominent with KCl than that with BaCl_2 .

Gamboge sol.

The results in Table XXVI have been obtained when gamboge sol is coagulated with a mixture of KCl and BaCl_2 .

TABLE XXVI

Concentration of the sol = 0.388 gm. gamboge per litre.

Amount of sol taken each time = 5 c.c.

Volume = 10 c.c.; Time = 1 hour.

2N KCl added in c.c.	N/5 BaCl_2 to complete coagulation in c.c.			
	Observed	Calculated	Difference	% Difference
0	0.90	—	—	—
0.90	0	—	—	—
0.10	0.95	0.80	0.15	18.8
0.20	1.00	0.70	0.30	42.9
0.30	0.85	0.60	0.25	41.7
0.40	0.75	0.50	0.25	50.0
0.50	0.60	0.40	0.20	50.0

The results in Table XXVI show that marked 'ionic antagonism' occurs when the sol is coagulated with a mixture of KCl and BaCl_2 . The behaviour of this sol is exactly similar to that of gum dammar sol.

It has been already reported that gamboge sol behaves abnormally on dilution.

Gold sol.

Coagulation of gold sol prepared according to the method of Donau with a mixture of electrolytes has been determined by Freundlich and Scholz. They have shown that when gold sol is coagulated with mixtures of electrolytes like LiCl and KCl , LiCl and MgCl_2 , LiCl and BaCl_2 , and LiCl and AlCl_3 , practically additive amounts of these electrolytes are required to coagulate the sol.

I have made some experiments on the coagulation of gold sol (prepared by Zsigmondy's method) by various pairs of electrolytes of which one has a stabilising effect. The results obtained are given in Tables XXVII-XXVIII.

TABLE XXVII

Concentration of the sol = 0.065 gm. gold per litre.

Amount of sol taken each time = 3 c.c.

Volume = 6 c.c.; Time = 1 hour.

Coagulation of gold sol with a mixture of KCl and $\text{K}_2\text{C}_2\text{O}_4$.

N/2 $\text{K}_2\text{C}_2\text{O}_4$ added in c.c.	N/2.5 KCl to complete coagulation in c.c.			
	Observed	Calculated	Difference	% Difference
0	0.90	—	—	—
1.70	0	—	—	—
0.2	1.25	0.79	0.46	58.2
0.4	1.30	0.69	0.61	88.4
0.6	1.20	0.58	0.62	107.0
0.8	0.95	0.48	0.47	98.3

TABLE XXVIII

Coagulation of gold sol with a mixture of KOH and KCl.

N/2 KOH added in c.c.	N/2.5 KCl to complete coagulation in c.c.			% Difference
	Observed	Calculated	Difference	
0	0.9	—	—	—
1.90	0	—	—	—
0.2	2.05	0.81	1.24	153
0.4	2.40	0.71	1.69	238
0.6	2.60	0.62	1.98	319
0.8	2.45	0.52	1.93	371

The results in Tables XXVII-XXVIII prove that marked 'ionic antagonism' exists when gold sol is coagulated with either a mixture of KCl and $\text{K}_2\text{C}_2\text{O}_4$ or KCl and KOH. This is because, as we have already stated, OH' and $\text{C}_2\text{O}_4''$ ions are appreciably adsorbed by negatively charged gold sol, which is consequently stabilised by this adsorption of ions carrying the same charge as the sol.

Silver sol.

We have determined the coagulation of silver sol prepared according to the method of Kohlschütter by various pairs of electrolytes and the results given in Table XXIX have been obtained.

TABLE XXIX

Concentration of the sol = 0.18 grm Ag per litre.

Amount of sol taken each time = 3 c.c.

Volume = 6 c.c.; Time = 1 hour.

N/8 KNO added in c.c.	N/625 $\text{Ba}(\text{NO}_3)_2$ for complete coagulation in c.c.			% Difference
	Observed	Calculated	Difference	
2.10	0	—	—	—
0	1.75	—	—	—
0.2	1.45	1.57	-0.12	-7.6
0.4	1.35	1.40	-0.05	-3.6
0.6	1.20	1.22	-0.02	-1.6

These results show that silver sol behaves normally towards a mixture of electrolytes like KNO_3 and $\text{Ba}(\text{NO}_3)_2$, but we have already observed that this sol behaves abnormally towards dilution when coagulated by KNO_3 . This behaviour of silver sol on dilution is, therefore, not in agreement with our results obtained here on the coagulation of this sol with a mixture of electrolytes. We are of opinion that the abnormal behaviour observed with silver sol is not primarily due to the adsorption of similarly charged NO_3' ions from KNO_3 , but due to the presence of OH' ions in the sol, which exert a great stabilising influence.

We have already shown that the abnormality of silver sol on dilution is more developed when it is coagulated with NaOH than that observed with KNO_3 . We shall now show in Table XXX that in presence of OH' ions silver sol shows more abnormality on dilution towards it; coagulation with KNO_3 .

TABLE XXX

Concentration of the sol = 0.08 grm. Ag per litre.

Sol A = 4 c.c. of the sol made up to 8 c.c.

Immediate colour change is observed.

Concentration of the sol	N/8 KNO ₃ to coagulate in c.c.	N/8 KNO ₃ to coagulate in c.c. in presence of 0.5 c.c. N/5 NaOH
A	0.80	0.70
$\frac{3A}{4}$	0.90	1.40
$\frac{A}{2}$	1.10	1.60

These results, therefore, show that the sol becomes more stable on dilution in presence of OH' ions than when no OH' ions are present.

Acclimatization

In previous papers¹ we have shown that the phenomenon of acclimatization is more developed with sols like arsenious sulphide, prussian blue, mastic, etc., than with ferric hydroxide (positive and negative) when coagulated by KBrO₃, BaCl₂, etc. On the other hand, we have observed well-marked acclimatization when a positively charged sol of ferric hydroxide is coagulated by Al(NO₃)₃, FeCl₃, etc. Moreover, we have proved that, in the coagulation of arsenious sulphide sol, *smaller* quantities of strychnine hydrochloride, quinine hydrochloride, and crystal violet are necessary to coagulate the sol when the addition is slow than when it is rapid. We have called this interesting phenomenon '*negative acclimatization*'. We have advanced a satisfactory explanation of this phenomenon as well as the phenomenon of positive acclimatization first observed by Freundlich.

In this paper we shall present the results obtained on this phenomenon with several other sols.

(1) With gum dammar sol the following results are obtained:—

When N KNO₃ is added very rapidly to 9 c.c. of the sol containing 0.483 grm of gum dammar per litre the sol requires 1.20 c.c. of the electrolyte for complete coagulation in an hour. On the other hand, when N KNO₃ is added 0.2 c.c. at a time after every twenty four hours with a shaking so as to mix up the electrolyte well, the same amount of the sol requires 1.85 c.c. of N KNO₃ for complete coagulation in one hour after the last addition of the electrolyte.

Similarly, when N/5 SrCl₂ is added all at once to 9 c.c. of the gum dammar sol, it requires 0.6 c.c. of the electrolyte for complete coagulation in an hour. If, however, 0.1 c.c. of the electrolyte is added every twenty four hours, the sol requires 0.8 c.c. of N/5 SrCl₂ to coagulate the sol completely in one hour after the last addition of the electrolyte.

Hence, it is apparent that the phenomenon of acclimatization is markedly developed when gum dammar sol is coagulated by either KNO₃ or SrCl₂.

(2) I have also studied the phenomenon of acclimatization when aluminium hydroxide sol is coagulated by KCl, K₂C₂O₄, K₄Fe(CN)₆ and potassium citrate. 4 c.c. of the sol containing 0.60 grm. of Al₂O₃ per litre are taken in

¹ Ghosh and Dhar: J. Phys. Chem., 29, 435, 659 (1925); Kolloid-Z., 38, 141 (1926).

clean test tubes and small quantities of various electrolytes are added from time to time. After each addition of the electrolytes, the test tubes are shaken to ensure mixing and complete coagulation is observed after one hour of the last addition of the electrolyte. The amounts of various electrolytes required to coagulate the same amount of the sol in an hour when added all at once were also determined. The results are given in Table XXXI.

TABLE XXXI

Electrolyte	Amount added at a time in c.c.	Amount to coagu- late in c.c. (when added slowly)	Amount to coagu- late in c.c. (when added all at once)
KCl N/10	0.2	1.80	1.75
K ₂ C ₂ O ₄ N/400	0.2	1.20	1.25
K ₄ Fe(CN) ₆ N/2500	0.2	1.80	1.80
K ₃ Cit N/2,000	0.2	1.30	1.30

The foregoing results prove that the phenomenon of acclimatization is not developed when aluminium hydroxide sol is coagulated by KCl, K₂C₂O₄, K₄Fe(CN)₆ and K₃Cit. I have already reported that this sol behaves normally towards dilution when coagulated by these electrolytes and does not show 'ionic antagonism' when coagulated by various pairs of electrolytes.

(3) The coagulation of *vanadium pentoxide sol* by the slow addition of an electrolyte has been studied. 8 c.c. of this sol containing 0.92 gm. of V₂O₅ are used and the amount of an electrolyte required to coagulate the sol completely in an hour when added drop by drop in 6 days, and that required to coagulate the same volume of the sol in an hour when the electrolyte is added all at once are also determined.

The results obtained, when vanadium pentoxide sol is coagulated by various electrolytes, are given in Table XXXII.

TABLE XXXII

Electrolyte	Amount added at a time in c.c.	Amount to coagu- late when added drop by drop in six days	Amount to coagulate when added all at once
KCl N/10	0.1	1.45 c.c.	1.40 c.c.
BaCl ₂ N/500	0.1	1.45 c.c.	1.45 c.c.
Al(NO ₃) ₃ N/1,000	0.1	0.70 c.c.	0.70 c.c.

This sol, therefore, does not show the phenomenon of acclimatization appreciably.

TABLE XXXIII

4 c.c. of gold sol containing 0.065 gm. gold per litre are used at a time.

Electrolyte	Amount added at a time in c.c.	Amount to coagu- late when added drop by drop in six days	Amount to coagulate when added all at once
KCl N/5	0.2	2.00 c.c.	2.00 c.c.
BaCl ₂ N/50	0.2	0.90 c.c.	0.95 c.c.
K ₂ C ₂ O ₄ N/2	0.2	1.90 c.c.	1.70 c.c.
KOH N/2	0.2	2.30 c.c.	2.00 c.c.

(4) The phenomenon of acclimatization has been studied with gold sol by various electrolytes and the results are given in Table XXXIII.

It will be seen from the results in Table XXXIII that gold sol does not show any acclimatization when it is coagulated by either KCl or BaCl₂; on the other hand, the phenomenon is observable with either K₂C₂O₄ or KOH. This is because, as I have already indicated, the ions carrying the same charge as the sol are appreciably adsorbed by gold sol from K₂C₂O₄ or KOH.

(5) The following results have been obtained with *antimony sulphide sol* when coagulated by various electrolytes:—

5 c.c. of antimony sulphide sol containing grm. of Sb₂S₃ per litre were taken in clean test tubes and the volume was made up to 8 c.c. by adding water. The amounts of various electrolytes necessary to coagulate antimony sulphide sol by the rapid addition or slow addition were determined exactly in the same way as described for arsenious sulphide sol. The results are given in Table XXXIV

TABLE XXXIV

Electrolyte	Amount added at a time in c.c.	Amount to coagu- late when added drop by drop in six days	Amount to coagulate when added all at once
KCl N/4	0.1	1.25 c.c.	1.10 c.c.
BaCl ₂ N/100	0.1	1.65 c.c.	1.25 c.c.
Strychnine hydrochloride	0.2	1.20 c.c.	1.35 c.c.
Methylene blue	0.2	2.40 c.c.	3.50 c.c.

The sol shows the phenomenon of acclimatization when coagulated by either KCl or BaCl₂. On the other hand, the phenomenon of negative acclimatization is developed when the sol is coagulated by either a dye-stuff like methylene blue or an alkaloid like strychnine hydrochloride. These results are exactly similar to those obtained with arsenious sulphide sol when coagulated by dye-stuffs and alkaloids. I am of opinion that the 'negative acclimatization' shown by antimony sulphide sol when coagulated by either a dye-stuff or an alkaloid is due to the fact that just like arsenious sulphide, antimony sulphide can appreciably adsorb these substances.

(6) I have observed the phenomenon of acclimatization with negatively charged manganese dioxide sol and the results are given in Table XXXV.

TABLE XXXV

2 c.c. of the sol containing 0.81 grm. of MnO₂ per litre made up to 7 c.c.

Electrolyte	Amount added at a time in c.c.	Amount to coagu- late when added in 5 days	Amount to coagu- late when added rapidly
KCl N/10	0.1	1.15 c.c.	1.15 c.c.
AgNO ₃ N/100	0.1	0.65 c.c.	0.72 c.c.
CuSO ₄ N/500	0.1	0.85 c.c.	1.05 c.c.

The phenomenon of acclimatization is not at all observed with KCl, on the other hand, the sol shows 'negative acclimatization' when coagulated by Ag⁺ and Cu⁺⁺ ions, which are highly adsorbed.

(7) The observations on phenomenon of acclimatization studied with positively charged manganese dioxide sol are given in Table XXXVI.

TABLE XXXVI

2 c.c. of the sol containing 0.91 grm. of MnO_2 per litre made up to 7 c.c.

Electrolyte	Amount added at a time in c.c.	Amount to coagu- late when added in 5 days	Amount to coagu- late when added rapidly
KCl N/20	0.1	1.9 c.c.	1.8 c.c.
AgNO_3 N/2.725	0.1	1.45 c.c.	1.2 c.c.
CuCl_2 N	0.1	0.75 c.c.	0.65 c.c.

It is apparent that the phenomenon of acclimatization is observed with all the three electrolytes but more markedly with Cu and Ag ions. The high adsorption of Cu and Ag ions by the positively charged manganese dioxide partially stabilises the sol. Consequently, the phenomenon of 'positive acclimatization' is observed in the coagulation of positively charged MnO_2 sol by AgNO_3 and CuCl_2 .

From the researches of Freundlich¹ we know that the cations of dye-stuffs like magenta, crystal violet, etc., and cations from strychnine nitrate, quinine hydrochloride, etc., are highly adsorbed by arsenious sulphide. In other words, the ratio of the adsorption of the anions to that of the cations is extremely small. Moreover we know that the percentage of adsorption by a definite weight of an adsorbent is greater from a dilute solution than from a stronger one. Hence the amount of the adsorption of the coagulating ion is greater when the addition is dropwise than when it is added all at once, because adsorption occurs at first from a very dilute solution of the electrolytes when it is added drop by drop. It therefore follows that when the adsorption of the ion carrying the same charge as the sol is much smaller than that of the ion carrying the opposite charge, the amount of electrolyte necessary to coagulate a given amount of sol will always be less when the addition is slow than when it is rapid. On the other hand, sols like mastic, As_2S_3 , prussian blue, etc., when coagulated by KCl, BaCl_2 , etc., require larger quantities of these electrolytes when the addition is slow than when it is rapid. I have already explained this phenomenon from the point of view of adsorption of ions carrying the same charge as the sol.

I have carried on quantitative experiments on the adsorption of barium ions by arsenious sulphide sol, when the addition of the electrolyte is rapid and slow. The following results were obtained:—

40 c.c. of arsenious sulphide sol is mixed with 50 c.c. of water and 10 c.c. of BaCl_2 N/25 is added all at once. The mixture is shaken well and left for 24 hours, when 60 c.c. of the clear solution is taken out and the concentration of Ba ion existing in the solution is determined as BaSO_4 . To another 40 c.c. of arsenious sulphide sol is added 50 c.c. of water and then 10 c.c. of BaCl_2

¹ Compare "Kapillarchemie," 582 (1921).

N/25 is added in a period of 6 days, 1 c.c. of the electrolyte being added at a time. The final concentration of Ba ion is determined from 60 c.c. of the clear solution.

In both the experiments the same pipettes and 100 c.c. flasks are used. The results given in Table XXXVII are the mean of two observations:—

TABLE XXXVII

Adsorption of Ba ion by arsenious sulphide sol from BaCl₂ solution.

Amount of arsenious sulphide = 0.4218 gm.

Volume = 100 c.c.

No.	Original concentration of Ba ion as BaSO ₄	Final concentration of Ba ion as BaSO ₄	Amount adsorbed as BaSO ₄	Amount adsorbed as Ba in millimoles

No. 1 gives the result obtained when BaCl₂ solution is added rapidly, whilst No. 2 gives the result when BaCl₂ solution is added slowly.

It is clear from Table XXXVII that the adsorption of Ba ion is greater when the addition is slow than that when it is rapid. These results clearly show that the view advanced in this paper to explain the phenomenon of acclimatization is correct and that the explanation of Bancroft is unsound, because according to his views the adsorption of barium ion should have been *less* when the addition is slow than when it is rapid, provided the amount of electrolyte added is the same in both the cases.

From our experimental results it is, therefore, evident that sols can be divided into two distinct classes one of which is normal whilst the other class is abnormal when coagulated by a mixture of electrolytes, Table XXXVIII.

TABLE XXXVIII

Abnormal	Normal
As ₂ S ₃ , Sb ₂ S ₃ , S(Odén), prussian blue, mastic, gum dammar, and gamboge.	MnO ₂ (positively and negatively charged), Sn(OH) ₄ (positively and negatively charged), Cr(OH) ₃ (positively and negatively charged), Fe(OH) ₃ (positively and negatively charged), Al(OH) ₃ , Th(OH) ₄ , V ₂ O ₅ , S(Weimarn), Au, Ag, & uranium ferrocyanide.

From Table XXXVIII it will be seen that those sols, which are classed as normal follow the general dilution rule, whilst sols that are abnormal do not follow the general dilution rule. Moreover, we have shown that sols of arsenious sulphide, antimony sulphide, mastic, gum dammar, and prussian blue show the phenomenon of acclimatization markedly when coagulated by

KCl, BaCl₂, etc., whilst sols of ferric hydroxide positively and negatively charged, manganese dioxide positively and negatively charged, aluminium hydroxide, vanadium pentoxide and gold do not show the phenomenon appreciably when coagulated by KBrO₃, KCl, K₂SO₄, etc. We have therefore, suggested that (i) abnormal dilution effect (ii) abnormal behaviour when coagulated by mixtures of electrolytes of widely varying precipitating powers (iii) the phenomenon of acclimatization, and the decrease in the viscosity of a sol when small quantities of electrolytes are added, are intimately connected and go hand in hand, and are mainly due to the adsorption of an ion carrying the same charge as the sol.

With the foregoing pages were ready for communication, Weiser¹ published a paper in which he has adversely criticised our views. We shall briefly point out the weakness of Weiser's arguments and emphasise the advances made from results obtained from this laboratory in our knowledge of the phenomenon of the coagulation of sols.

We have shown that, when an ion carrying the same charge as the sol is not appreciably adsorbed, the general dilution rule is obeyed, i.e. the greater the concentration of the sol the greater is the amount of an electrolyte necessary for coagulation irrespective of the valency of the precipitating ion. This general dilution rule has been found to be applicable to sols of ferric hydroxide (positive and negative), stannic hydroxide (positive and negative), chromium hydroxide (positive and negative), manganese dioxide (positive and negative), thorium hydroxide, aluminium hydroxide, gold, sulphur (Weimarn) and vanadium pentoxide, when coagulated by such electrolytes as possess an ion carrying the same charge as the sol which is not appreciably adsorbed by the sol.

The adsorption of an ion carrying the same charge as the sol is specific and is different for different ions and sols. It must be emphasised here, therefore, that the influence of ions carrying the same charge as the sol is certainly specific and is only observable with some definite sols when coagulated by a definite electrolyte.

In a previous paper, we have shown that when ferric hydroxide sol is coagulated by KCl or KBrO₃ the sol follows the general dilution rule because the adsorption of the similarly charged potassium ions is not appreciable and does not interfere with the effect of the oppositely charged ions Cl' or BrO₃', and the phenomenon of coagulation observed here is a normal one. On the other hand, when ferric hydroxide sol is coagulated by either HCl or Al(NO₃)₃ or FeCl₃, besides the influence of oppositely charged ions, the effect of ions bearing the same charge as the sol is also prominent and the coagulation in this case is not so simple as with KCl or KBrO₃, when Cl' and BrO₃' ions bring about coagulation and the potassium ions do not appreciably interfere with the coagulation process.

Our experimental results in the coagulation of Fe(OH)₃ sol at various dilutions by HCl, FeCl₃ and Al(NO₃)₃ conclusively prove that in these cases the dilute sol becomes more stable than a concentrated one for these electro-

¹ J. Phys. Chem., 30, 20 (1926).

lytes simply because the influence of similarly charged ions is very marked; on the other hand, the general dilution rule is followed by the same sol, when coagulated by either KCl or KBrO_3 . Hence these results prove that the abnormal dilution effect is undoubtedly connected with the adsorption of the similarly charged ions, and if this influence is not appreciable, which should generally be the case, the general dilution rule is obeyed. It seems, therefore, rather peculiar that Weiser has cited these results as a serious objection to our general dilution rule, which must be obeyed by the sol in case the specific influence of ions carrying the same charge as the sol does not interfere in the coagulation of the sol by the oppositely charged ion.

From a survey of our experimental results, it will be observed that the adsorption of ions carrying the same charge as the sol is specific and is only observable with certain sols for some definite electrolytes and is not as general as the charge neutralization of a sol by the oppositely charged ions.

From some experiments on the coagulation of a few sols at various dilutions by different electrolytes Burton and Bishop¹ concluded:—

1. For univalent ions the concentration of ion necessary to produce coagulation increases with the decreasing concentration of the sol.
2. For divalent ions the concentration of ion necessary to produce coagulation is almost constant and independent of the concentration of the colloid and
3. For trivalent ions the concentration of ion necessary to produce coagulation varies almost directly with the concentration of the colloid.

In several publications we have shown that these deductions of Burton and Bishop are not generally applicable and cannot be observed with a sol which has no chemical affinity for similarly charged ions; consequently we enunciated the general dilution rule, and have completely established that the rule is strictly applicable, when the adsorption of the similarly charged ions is not appreciable and does not interfere with the effect of the oppositely charged ions. It need hardly be said here, again, that the general dilution rule is applicable not only to all sols that do not adsorb similarly charged ions appreciably but as well to those sols, which appreciably adsorb similarly charged ions, when coagulated by polyvalent precipitating ions.

Weiser has also studied the influence of dilution of a sol on its coagulation by different electrolytes and he has remarked that "if stabilising ion is adsorbed, a greater concentration of precipitating ion will be required to produce coagulation. This effect will be more pronounced the greater the dilution of the colloid, since the decreased chance both of collision and coalescence will combine to render the colloid proportionately more stable so that proportionately more of the precipitating ion must be added for complete precipitation." Thus it will be seen that Weiser has given prominence to (1) influence of similarly charged ions and (2) the increase in distance between colloid particles, in explaining the abnormal behaviour of some sols on dilution. In previous papers we have clearly shown that the increase in the dis-

¹ J. Phys. Chem., **24**, 701 (1920).

tance between colloid particles on dilution can in no way explain the abnormal dilution effect. Thus we have shown, in the coagulation of arsenious sulphide sol by well-washed freshly precipitated barium sulphate, the rule that the greater the concentration of the sol, the greater the concentration of the precipitating agent, is followed, because coagulation in this case being only mechanical in nature, the question of similarly charged ions does not arise. It is rather surprising to find that Weiser in his latest paper has considered the decreased chance of collision as an important factor for the greater stability of a sol on dilution but he made the following observations in a previous paper:—"The decreased chance of collision of particles produced by diluting colloidal As_2S_3 cannot be compensated by adding an amount of KCl sufficient to precipitate the undiluted colloid and allowing to stand a reasonable time". His experiments distinctly prove that the above abnormal behaviour of arsenious sulphide when coagulated by KCl persists even when the decreased chance of coagulation is compensated by increasing the time of standing. Consequently there is a considerable confusion of thought about this point in Weiser's writings.

We have definitely proved in previous papers that when KCl , which behaves abnormally towards the coagulation of As_2S_3 and Sb_2S_3 when diluted, is used as the coagulating agent, diluted sols of the same substances do not coagulate even after the lapse of 16 hours when sufficient electrolyte is added to coagulate the concentrated sols in an hour. In the same paper we came to the conclusion that the view advanced by Kruyt and Spek, and by Mukherji and Sen that the decreased chance of collision amongst the colloidal particles is an important factor that prevents a weaker sol of arsenious sulphide from coagulating is not corroborated by experiments.

It must be remarked that Weiser has ascribed the variation of the precipitation value of an electrolyte on diluting a colloid to the relative adsorbability of the precipitating ions and the stabilising ion, without assigning definite reasons. From theoretical considerations we have concluded that the abnormal behaviour of a sol on dilution is due to the greater adsorption of the similarly charged ion by the dilute sol than the concentrated one. It has been shown that the abnormal behaviour of a sol on dilution is observed when the ratio of the adsorption of the ion carrying the same charge as the sol to that of the ion carrying the opposite charge goes on increasing as the sol is diluted. We have proved experimentally in the previous paper that positively charged manganese dioxide sol behaves abnormally on dilution when coagulated by AgNO_3 or CuCl_2 , and that the ratio of the adsorption of positive ions to negative ions actually decreases with the decreasing concentration of the sol. Hence, our explanation of the abnormal behaviour of sols on dilution is not a matter of conjecture only but is supported by experimental evidence. We venture to think that this is a distinct advance in our knowledge of the phenomenon of coagulation.

We have repeatedly emphasised that the so-called 'ionic antagonism' observed when certain sols are coagulated by mixtures of electrolytes is not mainly due to the opposing influences of the coagulating ions, but is mainly

caused by the preferential adsorption of an ion carrying the same charge as the sol. Thus, we have shown that marked 'ionic antagonism' exists when arsenious sulphide, antimony sulphide, prussian blue, mastic, gamboge, gum dammar, etc. are coagulated by mixtures like KCl and BaCl₂, NaCl and SrCl₂, etc., simply because these sols are capable of adsorbing an ion carrying the same charge as the sol. In order to substantiate our views we have made further experiments in the coagulation of various other sols with a suitable pair of electrolytes, where one of them can give out such a similarly charged ion as can be appreciably adsorbed by the sols. In all cases so far studied we have found that the nature of 'ionic antagonism' is exactly similar to that observed with arsenious or antimony sulphide sols, when coagulated by KCl and BaCl₂, NaCl and SrCl₂ etc. For example, we have noted that marked 'ionic antagonism' is observed when ferric hydroxide sol (positive) is coagulated by a mixture of Al(NO₃)₃ and K₂SO₄; when negatively charged manganese dioxide sol is coagulated by KOH and KCl; when positively charged manganese dioxide sol is coagulated by AgNO₃ and KNO₃, CuCl₂ and KNO₃; when gold sol is coagulated by mixtures like KOH and KCl, K₂C₂O₄ and KCl; when uranium ferrocyanide sol is coagulated by mixtures of K₄Fe(CN)₆ and KCl; when sols of ferric hydroxide, chromium hydroxide, aluminium hydroxide are coagulated by mixture of HCl and KCl, HCl and K₂SO₄, etc.; when arsenious sulphide sol is coagulated by mixtures like KHCO₃ and KCl, NaNO₂ and KCl, C₆H₅COONa and KCl, NaNO₂ and BaCl₂, etc. This is certainly because stabilisation of these sols is effected by the adsorption of similarly charged ions, and in several of these cases, no ionic antagonism of the precipitating ions is possible, because the precipitating ion is the same in both the electrolytes.

It is well known that ferric hydroxide sol can appreciably adsorb Fe⁺⁺⁺ ions, negatively charged manganese dioxide sol OH⁻ ions, positively charged manganese dioxide sol Ag⁺ or Cu⁺⁺ ions, and gold sol C₂O₄^{''} or OH⁻ ions. Moreover, we have shown that when ferric hydroxide sol is coagulated by FeCl₃, when positively charged manganese dioxide sol is coagulated by either AgNO₃ or CuCl₂, when negatively charged manganese dioxide sol is coagulated by KOH, or when gold sol is coagulated by either KOH or K₂C₂O₄, these sols show abnormal behaviour on dilution, because in these cases complication arises from the marked adsorption of ions carrying the same charge as the sols. It is, therefore, evident that the property of the sols of arsenious sulphide, antimony sulphide, prussian blue, mastic, etc. to develop 'ionic antagonism' when coagulated by mixtures of KCl and BaCl₂ or KCl and SrCl₂ is unquestionably due to the adsorption of an ion bearing the same charge as the sol. It is interesting to note that more marked 'ionic antagonism' is observed when a sol of ferric hydroxide is coagulated by FeCl₃ and K₂SO₄ or Al(NO₃)₃ and K₂SO₄ than when sols of As₂S₃, Sb₂S₃, mastic, etc. are coagulated by KCl and BaCl₂, KCl and SrCl₂, etc. This is due to the fact that the adsorption of similarly charged ions from KCl in the latter case is not so great as the adsorption of similarly charged ions like Fe⁺⁺⁺, Al⁺⁺⁺, etc. by a sol of ferric hydroxide.

In one of the communications on this subject we have shown that in the coagulation of antimony sulphide sol by a mixture of electrolytes like KCl and BaCl₂, the adsorption of Ba ion is markedly cut down by the presence of K ion and vice versa. An interesting fact was, however, obvious from these results that the sum of the adsorption of potassium and barium ions expressed as equivalents by Sb₂S₃ sol is greater than the adsorption of barium ion by Sb₂S₃ sol, when coagulated by BaCl₂ alone, but less than the adsorption of K⁺ ion when coagulated by only KCl. This is certainly due to the fact that more chloride ions are adsorbed by Sb₂S₃ sol when coagulated by a mixture of KCl and BaCl₂ than the amount adsorbed by the sol when coagulated by BaCl₂ alone, because the concentration of chloride ions is always greater when the sol is coagulated by a mixture of KCl and BaCl₂ than when BaCl₂ is used alone; consequently, more of the cations taken together must be required to cause complete coagulation. On the other hand, when the sol is coagulated by only KCl, the concentration of Cl⁻ ion is always greater than its concentration when mixtures of KCl and BaCl₂ are used. Hence more stabilisation is observed and consequently more of the cations are necessary to bring about charge neutralisation when the sol is coagulated by KCl alone than that observed when coagulated by mixtures of KCl and BaCl₂.

When arsenious sulphide sol is coagulated by BaCl₂ alone, the concentration of the similarly charged Cl⁻ ions being very small, they cannot exert a marked stabilising influence. On the other hand, when the sol is coagulated by KCl, the concentration of KCl necessary to coagulate the sol is far greater than that of BaCl₂, and consequently the concentration of Cl⁻ ion being large in case of KCl, exert a greater stabilising influence than that observed with BaCl₂. Now, when a sol of As₂S₃ is coagulated by a mixture of KCl and BaCl₂, the concentration of Cl⁻ ions being far greater than that when the sol is coagulated by only BaCl₂, more stabilisation takes place and greater amounts of BaCl₂ are necessary to coagulate the sol in presence of KCl. This stabilisation should increase as the concentration of Cl⁻ ion is gradually increased by adding increasing amounts of KCl. But as a matter of fact this process cannot proceed very far as the increase in Cl⁻ ion concentration is also associated with an increase in the concentration of potassium ions, which have a coagulating effect. If the increase in Cl⁻ ion concentration is effected by LiCl, it is expected that greater stabilisation should be observed with this electrolyte as Li⁺ ion possesses smaller coagulating effect than K⁺ ion.

We are, therefore, of the opinion that 'ionic antagonism' observed in the coagulation of sols like arsenious sulphide, antimony sulphide by a mixture of electrolytes like KCl and BaCl₂ or NaCl and SrCl₂ is more due to the similarly charged Cl⁻ ions, than to the cutting down of the adsorption of Ba⁺⁺ or Sr⁺⁺ ions by K⁺ or Na⁺ ions. In his recent paper Weiser, however, has remarked that "the greater precipitation value of BaCl₂ in presence of LiCl or KCl was thought to be due chiefly to the cutting down of the adsorption of each precipitating ion by the presence of the other". We, however, believe that this cutting down of adsorption can in no way explain Weiser's own results on 'ionic antagonism' with As₂S₃ sol. Thus 'ionic antagonism' observed

for the mixtures of LiCl and BaCl₂, NaCl and BaCl₂ and KCl and BaCl₂ is in the following order in presence of alkali chlorides, LiCl > NaCl > KCl, the maximum antagonism being observed with LiCl and the least with KCl. The experimental results of Weiser show that cutting down of adsorption of barium ions is more marked in presence of K⁺ ions than in presence of Li⁺ ions, and according to the views of Weiser the precipitating concentration of BaCl₂ will be less in presence of LiCl than in presence of KCl, but Weiser's own results are contrary to the above expectations. In order to explain away this anomalous behaviour Weiser has made the following remarks, "Hand in hand with this, the decrease in the adsorption of alkali by barium, which will tend to make the precipitation concentration of barium chloride higher in presence of lithium."

It is to be noted here that up till now Weiser has made no experiments in the cutting down of adsorption of alkalies by barium ions. In a previous paper we have proved that the adsorption of K⁺ ions is decreased to the same extent in presence of barium ions as that observed for barium ions in presence of K⁺ ions. It must be emphasised that as the coagulating power of Ba⁺⁺ ions is about 50 times greater than that of K⁺ or Li⁺ ions, a slight difference in the cutting down of adsorption of K⁺ or Li⁺ ions in presence of Ba⁺⁺ ions, should not affect the precipitation value of BaCl₂. Hence, we are of the opinion that the views of Weiser as quoted above are totally inadequate to explain his results. On the other hand, our explanation of this behaviour is the following and seems more sound:—

It is well known that the coagulating power of K⁺ ions is appreciably greater than that of Li⁺ ions; in other words, greater quantities of LiCl will be required than KCl to coagulate a sol of As₂S₃. Now, if the coagulation is effected by mixtures of KCl and BaCl₂, and LiCl and BaCl₂ and when the amounts of KCl and LiCl added are exactly equal, it is self-evident that the amount of BaCl₂ necessary to coagulate the sol will be greater in the case of LiCl than in the case of KCl.

Weiser is of the opinion that the phenomenon of 'ionic antagonism' is due more to the cutting down of adsorption of one of the precipitating ion in presence of the other, than to the adsorption of ions carrying the same charge as the sol. Moreover, he believes that the mechanism of 'ionic antagonism' observed with arsenious sulphide when coagulated by a mixture like KCl and BaCl₂ or LiCl and BaCl₂, is not of the same type as observed with ferric hydroxide sol when coagulated by a mixture Al(NO₃)₃ and K₂SO₄, or when cupric ferrocyanide sol is coagulated by a mixture of K₄Fe(CN)₆ and KCl or BaCl₂, or when uranium ferrocyanide sol is coagulated by a mixture of K₄Fe(CN)₆ and KCl. From our researches it will be absolutely clear that the nature of 'ionic antagonism' developed in all these cases is essentially the same, the only difference being that 'ionic antagonism' observed in the coagulation of ferric hydroxide sol by a mixture of Al(NO₃)₃ and K₂SO₄ and in ferrocyanide sols by a mixture of K₄Fe(CN)₆ and KCl is usually more developed than that observed in the coagulation of arsenious sulphide sol by a mixture of KCl and BaCl₂, simply because the adsorption of the similarly

charged ions is in larger amounts in the case of the sols of ferric hydroxide and ferrocyanide than that of Cl^- ions by arsenious sulphide.

We have already shown that the increase in the adsorption of one ion in presence of another can in no way consistently explain all the results in the coagulation of sols by a mixture of electrolytes. Moreover, we are of the opinion that this decrease in adsorption of one precipitating ion in presence of another is a general phenomenon and should be observed with all sols and freshly precipitated substances.

It seems probable that the phenomenon of cutting down of adsorption of a precipitating ion should be more pronounced with those sols or freshly precipitated substances, which are not good adsorbents than with those sols or precipitates, which are powerful adsorbents. It is well known that the phenomenon of cutting down of adsorption is readily observed with sols like As_2S_3 , Sb_2S_3 and these sols cannot adsorb cations highly. On the other hand, the hydroxides of iron, chromium, aluminium are far better adsorbents of anions than these sulphides and the decrease in adsorption of one ion in presence of another is not much noticeable at small concentrations of added electrolytes with the hydroxide sols. Weiser's own experiments on the adsorption of anions by $\text{Fe}(\text{OH})_3$ sol show that the adsorption of $\text{C}_2\text{O}_4^{2-}$ ion in presence of SO_4^{2-} ion is decreased more than 30 percent as the concentration of SO_4^{2-} ion is increased. Exactly similar results were obtained by Weiser with chromium hydroxide sol and KCl and $\text{K}_2\text{C}_2\text{O}_4$. It is well known that additive relationships are observed when ferric hydroxide sol is coagulated by a mixture of KCl and $\text{K}_2\text{C}_2\text{O}_4$, and K_2SO_4 and $\text{K}_2\text{C}_2\text{O}_4$, and chromium hydroxide sol is coagulated by KCl and $\text{K}_2\text{C}_2\text{O}_4$. We are making further experiments to show that the decrease in adsorption of a precipitating ion in presence of another is a general phenomenon and can be observable with all sols. It is, therefore, very difficult to follow the reasoning of Weiser that 'ionic antagonism', which is observed with only a few specific sols and a particular set of electrolytes, originates from a general phenomenon, viz. the cutting down of adsorption of a precipitating ion in presence of another.

We have always emphasised that the adsorption of similarly charged ions can satisfactorily explain all 'ionic antagonism' so far observed. It is, however, gratifying to observe that Weiser also emphasises the adsorption of similarly charged ions by arsenious sulphide as a fundamental factor in causing the decrease in the adsorption of a coagulating ion in presence of another, in explaining 'ionic antagonism', which is observed in the coagulation of As_2S_3 sol by KCl and BaCl_2 , NaCl and BaCl_2 , etc.

We are definitely of the opinion that the adsorption of ions carrying the same charge as the sol is a far more important factor than the cutting down of adsorption, as an explanation of the so-called 'ionic antagonism' when sols are coagulated by mixtures of electrolytes. We have already emphasised in the foregoing pages that the negatively charged manganese dioxide sol shows additive relationship when coagulated by mixture of electrolytes of varying valencies. Consequently, from the point of view of Weiser, who is of opinion that cutting down of the adsorption is the most important factor, when the

sol or a precipitate of manganese dioxide is treated with a mixture of either KCl and CuCl_2 or NH_4NO_3 and AgNO_3 , the presence of K^+ ions or NH_4^+ ions should not cut down the adsorption of Cu^{++} or Ag^+ ions. The experimental results in Table XXXIX with precipitated manganese dioxide, however, prove that marked decrease of the adsorption of both Cu^{++} and Ag^+ ions occurs in presence of K^+ and NH_4^+ ions respectively.

TABLE XXXIX

Sample of hydrated manganese dioxide contains 74% MnO_2 and 26% water.

Weight of manganese dioxide used for each adsorption experiments = 0.5 grm.

Volume = 50 c.c.

Initial concentration of the electrolytes = 10 millimoles in 50 c.c

Electrolyte added		Amount adsorbed in millimoles	
A	B	A	B
AgNO_3	—	2.00	—
AgNO_3	NH_4NO_3	1.88	—
CuCl_2	—	0.82	—
—	KCl	—	1.25
CuCl_2	KCl	0.52	0.33

In a recent paper Weiser has shown that no 'ionic antagonism' is observed when a sol of arsenious sulphide is coagulated by a mixture of KCl and $\text{Ce}(\text{NO}_3)_3$, and he believes that this is due to the fact that the adsorption of Ce^{+++} ions is cut down to a lesser extent in presence of K^+ ions than that observed for Ba^{++} ions in presence of K^+ ions. From the experiments of Weiser, it will be seen that the adsorption of Ce^{+++} ions is cut down to the extent of more than 20%, when comparatively dilute solutions of KCl and $\text{Ce}(\text{NO}_3)_3$ are used. Moreover, it is expected from Weiser's line of argument that the adsorption of K^+ ions should be more markedly depressed in presence of Ce^{+++} ions than that expected in presence of Ba^{++} ions. It is well known that 'ionic antagonism' observed with arsenious sulphide sol for mixtures of KCl and BaCl_2 is sometimes as great as 90 percent, when the adsorption of Ba^{++} ions is cut down to an extent of 80 percent in presence of K^+ ions. Hence, it appears that if simply the cutting down of adsorption were the only important factor in the coagulation of a sol by a mixture of electrolytes, 'ionic antagonism' should have been observed with mixtures of KCl and $\text{Ce}(\text{NO}_3)_3$.

We have definitely shown in previous papers that small amounts of an acid render arsenious sulphide sol unstable to a marked extent towards all electrolytes. It is well known that $\text{Ce}(\text{NO}_3)_3$ is appreciably hydrolysed and HNO_3 is set free and hence no 'ionic antagonism' is observed when the sol is coagulated by a mixture of KCl and $\text{Ce}(\text{NO}_3)_3$, because of the presence of free nitric acid, which renders the sol unstable.

It has been observed in our former papers that no 'ionic antagonism' should be developed when arsenious sulphide sol is coagulated by a mixture

of two electrolytes of similar precipitating powers. For example, no ionic antagonism is observed when arsenious sulphide sol is coagulated by a mixture like MgCl_2 and BaCl_2 . When a sol of As_2S_3 is coagulated by a mixture like KCl and NaCl , it is apparent that the concentration of Cl' ions is practically the same when the sol is coagulated by either KCl and NaCl separately or with their mixtures; consequently, it is obvious that no 'ionic antagonism' should be observed when the sol is coagulated by a mixture of KCl and NaCl . Moreover, as fairly concentrated solutions of both KCl and NaCl are used, it is evident that in their mixtures the adsorption of both K and Na ions should be markedly cut down by the presence of one another, and hence according to the views of Weiser marked 'ionic antagonism' should have been observed in these cases.

It will be interesting to point out at this place that we have observed marked 'ionic antagonism' with a sol of arsenious sulphide when coagulated by mixtures like KHCO_3 and KCl , KNO_2 and KCl , etc., where the cations being the same in both the cases, it is very difficult to imagine the depression of the adsorption of cations and explain 'ionic antagonism'. Similarly Mukherji and Ghosh have observed that sufficient 'ionic antagonism' also exists when arsenious sulphide sol is coagulated by a mixture of $\text{K}_4\text{Fe}(\text{CN})_6$ and KCl . More or less similar results are obtained by Weiser in the coagulation of As_2S_3 sol with the same mixture of electrolytes. In all these cases 'ionic antagonism' developed has to be ascribed to the stabilisation of the sols by the highly adsorbed anions. We have already remarked that $\text{Fe}(\text{CN})_6'''$ ions are more adsorbed than Cl' ions by As_2S_3 sol.

It must be clearly stated here that the greater adsorption of $\text{Fe}(\text{CN})_6'''$ ion or citrate ion than Cl' ion by As_2S_3 sol originates from the chemical affinity of As_2S_3 for these anions. In a recent paper we have clearly shown that the applicability of the Schulze-Hardy law to the phenomenon of adsorption should necessarily be limited to the cases where it originates only from the electric attraction existing between the colloid particles and oppositely charged ions, and it is unwise to seek its applicability in the cases where the adsorption occurs due to the chemical affinity of the adsorbent for the adsorbing materials. It is a pity that Weiser believes that the Schulze-Hardy law should be applicable even to the adsorption of similarly charged ions by a sol.

In previous publications we have shown that the phenomenon of acclimatization, viz. that more of an electrolyte is necessary for coagulation than when it is added rapidly, is more pronounced with sols of arsenious sulphide, mastic, gum dammar, prussian blue, etc., when coagulated by KCl , BaCl_2 , etc. On the other hand, the phenomenon of acclimatization is not observable when ferric hydroxide sol (positive) is coagulated by KBrO_3 and manganese dioxide sol (positive) is coagulated by KCl , whilst enough of the phenomenon of acclimatization is developed when ferric hydroxide sol is coagulated by $\text{Al}(\text{NO}_3)_3$ and manganese dioxide sol is coagulated by either CuCl_2 or AgNO_3 . In order to explain these results we have emphasised that the phenomenon of acclimatization is mainly due to the adsorption of similarly

charged ions by the sol from the added electrolytes and hence the phenomenon of acclimatization is observable when a sol is coagulated by an electrolyte that can give out similarly charged ions, which are markedly adsorbed by the sol. We have found that our view is capable of explaining the observed results, and in a recent paper we have shown that the views of Freundlich, Bancroft, and Weiser on the phenomenon of acclimatization are inadequate.

In a very recent paper Weiser has cited three factors to explain the phenomenon of acclimatization, viz. (1) the extent to which the colloid undergoes fractional precipitation; (2) the adsorbing power of the precipitated colloid and (3) the adsorbability of the precipitating ions. The last factor has been recently modified to read (3) the relative adsorbability of the precipitating and stabilising ions. Weiser has recognised that strong adsorption of the stabilising ion is not essential in case there is strong adsorption of the precipitating ions during fractional agglomeration.

In a previous paper we have already shown that fractional precipitation is observable both with arsenious sulphide and ferric hydroxide sols. Moreover, it is well known that ferric hydroxide is a far better adsorbent than arsenious sulphide. Consequently, if Weiser's views (1 and 2) were correct more acclimatization should be observed with ferric hydroxide sol than that observed with arsenious sulphide sol, but experimental results show that reverse is the case.

If, however, Weiser's argument "that strong adsorption of the stabilising ion is important, *if not essential*, in case the successive dilutions of the sol by fractional precipitation is the determining factor," be correct, the phenomenon of acclimatization with arsenious sulphide sol should only be developed when the sol is coagulated by KCl, LiCl, NaCl, etc., because only with these univalent salts, greater quantities are required to coagulate a dilute sol than a concentrated one. On the other hand, from Weiser's point of view practically the same amount of BaCl_2 will be necessary to coagulate the sol when it is added slowly or rapidly because the coagulating power of BaCl_2 is independent of the concentration of the sol, whilst smaller quantities of $\text{Al}(\text{NO}_3)_3$, $\text{Ce}(\text{NO}_3)_3$, etc., should be necessary to coagulate the sol when added slowly, because it is well known that the amount of $\text{Al}(\text{NO}_3)_3$ or $\text{Ce}(\text{NO}_3)_3$ necessary to coagulate the sol decreases with the decreasing concentration of the sol. But as a matter of fact, we have shown that the phenomenon of acclimatization is developed when As_2S_3 sol is coagulated by either KCl or BaCl_2 or $\text{Al}(\text{NO}_3)_3$, and we are, therefore, led to conclude that Weiser's modification of the third factor causing the phenomenon of acclimatization is of no use in explaining the experimental results.

We have performed some experiments on the phenomenon of acclimatization of arsenious sulphide sol by electrolytes like strychnine hydrochloride, quinine hydrochloride, crystal violet, etc., from which the cations are highly adsorbed in comparison with that of the anions; consequently anions in these cases possess practically no effect. We have found that in all these cases investigated the amounts of the electrolytes necessary for coagulation are smaller when the addition is slow than when rapid. It will be also interesting

to point out that we observed more marked fractional precipitation when As_2S_3 sol is coagulated by quinine hydrochloride, strychnine hydrochloride, crystal violet, etc., than that observed when this sol is coagulated by KCl , BaCl_2 , $\text{Al}(\text{NO}_3)_3$, etc. Consequently, from Weiser's view of the removal of the coagulating ion by the partly agglomerated mass, it is expected that more marked acclimatization is to be observed with strychnine hydrochloride, quinine hydrochloride, crystal violet, etc., and the phenomenon of 'negative acclimatization' viz. *less* of a coagulating ion is necessary to precipitate the sol, when the addition is slow than when it is rapid cannot be even conceived from Weiser's point of view.

Moreover, it is difficult to see how an agglomerated mass can exert an adsorbing effect greater than the sol itself. There is no doubt that colloid particles are better adsorbents than their agglomerated mass, because the surface per unit mass of the same substance is greater when it is present as small colloid particles than when it is present as a coagulated mass. Moreover, the adsorbing capacity of colloid particles is due not only to its chemical affinity but also arises from their charge.

We venture to think that our experimental results and conclusions on the phenomenon of acclimatization mark a distinct advance in explaining the phenomenon.

In this connection we should like to point out that Weiser and Nicholas show that prussian blue sol behaves normally towards dilution when coagulated by KCl . At first, we made experiments on the coagulation of prussian blue by a mixture of electrolytes like KCl and BaCl_2 and observed that appreciable 'ionic antagonism' existed in this case, and we could immediately predict that the conclusions of Weiser and Nicholas are incorrect and the sol should be abnormal towards dilution when coagulated by KCl , K_2SO_4 , etc. Consequently, we extended our investigation on the influence of dilution of this sol towards its coagulation by KCl , BaCl_2 and found that the sol behaves abnormally towards dilution when coagulated by KCl . It must be said here that the sol showed positive acclimatization when coagulated by KCl , BaCl_2 , etc., and consequently it is needless to emphasise that the three phenomena are intimately associated.

Consequently, this correlation between these diverse phenomena is of great importance, because from an investigation of one of these phenomena, one can always predict with accuracy the other two phenomena.

It has already been said that when an electrolyte, say $\text{K}_4\text{Fe}(\text{CN})_6$, is added to a uranium ferrocyanide sol, the first effect is the adsorption of the similarly charged $\text{Fe}(\text{CN})_6^{4-}$ ion by the colloid particles and I have proved that this adsorption follows the general adsorption formula. If, therefore, the sol is diluted say twice, the amount of adsorption of $\text{Fe}(\text{CN})_6^{4-}$ ion from the same concentration of $\text{K}_4\text{Fe}(\text{CN})_6$ is certainly greater than half, so that the amount adsorbed per unit mass of the colloid is greater with the diluted sol than that with the concentrated one. Now, if the sol of uranium ferrocyanide is coagulated with a mixture of KCl and $\text{K}_4\text{Fe}(\text{CN})_6$ the 'ionic antagonism' which I have explained to be due to the stabilisation of the sol by the

preferential adsorption of $\text{Fe}(\text{CN})_6'''$ ion, should be more marked with a dilute sol than with a concentrated one. Moreover, according to my view a similar behaviour is expected when the sols of arsenious sulphide, antimony sulphide, mastic, etc., are coagulated by mixtures of KCl and BaCl_2 , LiCl and SrCl_2 , etc., or the sols of ferric hydroxide, chromium hydroxide, etc., are coagulated by mixtures of HCl and KCl, FeCl_3 and KCl, CrCl_3 and KCl etc. My results with prussian blue and uranium ferrocyanide sols greatly strengthen my view that the dilution effect and the behaviour towards a mixture of electrolytes are essentially connected and are mainly due to the same phenomenon of the adsorption of the ions bearing the same charge as the colloid particles.

It will be interesting to note that the cataphoretic experiments on arsenious sulphide sol carried on by different investigators are in general agreement with the view that ions carrying the same charge as the sol is adsorbed by the sol and partially stabilises it. Kruyt¹, Powis² and others have shown that the velocity of arsenious sulphide particles sometimes increases on the addition of electrolytes like KCl. Recently Freundlich and Zeh³ have shown with arsenious sulphide sol and potassium ferrocyanide that the velocity increases to the extent of 12%, and then steadily decreases, whilst in the case of ferric hydroxide sol with $[(\text{NH}_3)_4\text{CO} < \text{NH}_2 > \text{CO}(\text{NH}_3)_4]\text{Cl}_4$ the velocity increases only 1.9 per cent on the addition of the above salt to ferric hydroxide sol. These results conclusively support my view, which I have repeatedly emphasised that arsenious sulphide is a better adsorbent for negative ions than ferric hydroxide for positive ions. Burton⁴ has shown from cataphoretic experiments that the velocity of copper sol obtained by Bredig's method first increases with KCl and then decreases. Moreover, Burton and Bishop⁵ have observed that this sol behaves abnormally when coagulated by KCl. I am confident, that these two phenomena are essentially connected and are certainly due to the adsorption of K^+ ions by the positively charged sol, and its consequent stabilisation due to the adsorption of ions carrying the same charge as the sol.

The above results of cataphoretic experiments definitely prove that an increment of charge occurs when small quantities of electrolytes like KCl, $\text{K}_4\text{Fe}(\text{CN})_6$, etc., are added to the sols of arsenious sulphide, copper etc. Consequently the statement of Weiser that on adding a few drops of NaCl to a sol of arsenious sulphide the stability of the sol remains unchanged is incorrect.

Summary and Conclusion

(1) Marked ionic antagonism is observed when sols of ferric hydroxide, aluminum hydroxide, and chromic hydroxide are coagulated by mixtures like HCl and KCl, HCl and K_2SO_4 , HCl and $\text{K}_3\text{Fe}(\text{CN})_6$. Moreover, experimental

⁴ "Physical Properties of Colloidal Solutions," 167 (1921).

results have been adduced showing that the above sols are stabilised in presence of acids, due to the preferential adsorption of similarly charged hydrogen ions by the sols of $\text{Fe}(\text{OH})_3$, $\text{Al}(\text{OH})_3$ and $\text{Cr}(\text{OH})_3$.

(2) Aluminium hydroxide sol does not show ionic antagonism when coagulated by KCl and K_2SO_4 or KCl and $\text{K}_2\text{C}_2\text{O}_4$, but develops well marked ionic antagonism when coagulated by KCl and $\text{Al}(\text{NO}_3)_3$ due to the preferential of similarly charged aluminium ions.

(3) Hydrochloric acid exerts a greater stabilising influence on aluminium hydroxide sol prepared in the cold than on a sol of ferric hydroxide prepared from boiling solution of ferric chloride. The sol prepared in the boiling condition is more aged and has lost part of its reactivity.

(4) Positively charged thorium hydroxide sol does not show ionic antagonism when coagulated by a mixture of KBrO_3 and K_2SO_4 .

(5) Negatively charged manganese dioxide sol behaves normally when coagulated by mixtures like KCl and KBr , BaCl_2 and MgCl_2 , KBr and BaCl_2 , but shows well-marked ionic antagonism when coagulated by a mixture of KOH and KCl . It has been definitely proved that OH' ions are markedly adsorbed by manganese dioxide.

(6) Positively charged manganese dioxide sol is normal when coagulated by KNO_3 and K_2SO_4 , but develops marked ionic antagonism when coagulated by such mixtures as KNO_3 and AgNO_3 , KNO_3 and CuCl_2 , etc. We have proved that Ag' and Cu'' ions are markedly adsorbed by MnO_2 sol.

(7) Negatively charged vanadium pentoxide sol behaves normally when coagulated by KCl and BaCl_2 .

(8) Positively charged stannic hydroxide sol shows no ionic antagonism when coagulated by KCl and K_2SO_4 .

(9) Negatively charged uranium ferrocyanide sol behaves slightly abnormally when coagulated by a mixture of KCl and BaCl_2 , but it develops well marked ionic antagonism when coagulated by KCl and $\text{K}_4\text{Fe}(\text{CN})_6$. This antagonism is more marked with the dilute sols of uranium ferrocyanide than with concentrated sols. This is caused by the preferential adsorption of ferrocyanide ions by the uranium ferrocyanide sol.

(10) Sols of gamboge and gum dammar behave abnormally when coagulated by KCl and BaCl_2 . The ionic antagonism is more marked with both these sols than with mastic sol.

(11) Marked ionic antagonism has been observed when gold sol is coagulated by mixtures like KCl and $\text{K}_2\text{C}_2\text{O}_4$, KCl and KOH etc., because gold sol can adsorb negative ions like $\text{C}_2\text{O}_4''$, OH' , etc.

(12) Silver sol behaves normally when coagulated by KNO_3 and $\text{Ba}(\text{NO}_3)_2$ but the sol becomes more stable on dilution in presence of OH' ions than when no OH' ions are present.

(13) Sols of aluminium hydroxide, vanadium pentoxide, and gold do not appreciably show the phenomenon of positive acclimatization when coagulated by the slow addition of such electrolytes as KCl , $\text{K}_2\text{C}_2\text{O}_4$, K_4Fe

(CN)₆, BaCl₂, etc., but gold sol develops marked positive acclimatization when coagulated by the slow addition of KOH or K₂C₂O₄, because OH' and C₂O₄'' are adsorbed by gold sol.

(14) Antimony sulphide and gum dammar sols develop acclimatization when coagulated by KCl, KNO₃, BaCl₂, SrCl₂, etc., because the ions carrying the same charge as the sol are adsorbed by antimony sulphide and gum dammar

(15) Negatively and positively charged manganese dioxide sols, do not show the phenomenon of positive acclimatization when coagulated by KCl, but the positively charged sol develops acclimatization when coagulated by AgNO₃ or CuCl₂.

(16) Antimony sulphide sol shows negative acclimatization when coagulated by strychnine hydrochloride, methylene blue, etc., and negatively charged MnO₂ sol shows the same phenomenon when coagulated by AgNO₃ or CuCl₂. This is due to the fact that the adsorption of the oppositely charged ion in these cases is very high in comparison with that of the similarly charged ion.

(17) Experiments on adsorption have been advanced supporting our view and showing the inadequacy of the views of Freundlich, Bancroft, and Weiser on acclimatization.

(18) The phenomenon of the cutting down of the adsorption of a precipitating ion due to the presence of another seems to be a general phenomenon.

(19) (i) Abnormal dilution effect, (ii) abnormal behaviour when coagulated by mixtures of electrolytes of widely varying precipitating powers, (iii) the phenomenon of positive acclimatization and (iv) the decrease in the viscosity of a sol when small quantities of electrolytes are added are intimately connected and go hand in hand and are mainly due to the adsorption of an ion carrying the same charge as the sol.

CORRESPONDING STATES FOR THE ENTROPY OF ELEMENTS

BY B. BRUŽS

The thermodynamic function entropy has gained in its usefulness for the laboratory practice mainly by the establishment of the relation of entropy to probability and by the statement of the Third Law that its value at 0°K for crystalline substances is zero.

FIG. 1

The following considerations are intended to show that there is strong evidence in favour of believing that also in the field of states of aggregation the value of the absolute entropy may give some very important reference points.

Thanks to the work of Lewis, Gibson and Latimer¹ we are in possession of a fairly complete table of entropies for the elements at 298°K. It is an interesting fact that the plot of these entropies against the atomic number, Fig. 1, gives a curve which follows very closely the shape of the well known Lothar Meyer curves. In other words the entropies at 298°K are periodic functions of the atomic weight. On the other hand we know that a single temperature is a very arbitrary point for comparison, in fact a simple consideration will show that suppose we compared the atomic heats of elements at 50°K, the result would be: the specific heats of solids are periodic functions of the atomic weight. This is a statement the use of which can not be compared with the Law of Dulong and Petit.

¹ J. Am. Chem. Soc., **44**, 1008 (1922).

This leads us to the question whether there is not a more general point on the temperature scale which could be used for comparison of entropies. The melting point was selected. It must be stated however that unfortunately we are by far not always in possession of reliable data both for melting points as well as for specific heats, the two quantities necessary for our calculations. The values used in this paper are selected from Landolt and Börnstein (1923). Another unavoidable fault was the assumption of constancy of specific heats above 0°C. Considering these factors we have to count with an error of at least 10%. The entropy at the melting point was found in the following way

$$S_m = \int_0^m c_p d\ln T = \int_0^{298} c_p d\ln T + \int_{298}^m c_p d\ln T$$

or on the bases of our assumptions

$$S_m = S_{298} + 2.303 c_p \log T_m/298$$

where the values of Lewis and coworkers are used for S_{298} . Inspecting Table I we arrive at the striking result that the values of S_m obtained in this way show a fairly constant value of about 20 entropy units within the limit of the errors of the experimental data and the calculation.

90 Th	13.6	2120	6.4	12.5	26.1		
92 Ur	11.1	2100	6.7	13.0	24.1		

Note. The discrepancies in the case of S, Br and I must be due to chemical change, the same is probably true for Zn and Sn. For the values of Mo, W Ir and Th experimental data will probably be responsible. Br, I and Sn have an abnormal position also on the $\log T_b/T_m - N$ curve.

There are a few exceptions, where the value of S_m deviates from 20 more than we would expect, but most of these cases can be easily reduced to greater uncertainty of experimental data or also to the case that the elements under consideration undergo a *chemical* change; under these circumstances our generalizations could evidently not hold.

The fact of periodicity of S_{298} has been used to intrapolate the S_{298} 's for Se, Sb, Te, Bi (shown in brackets in the table) with the result that the calculated values of S_m gave good results. This example is shown to indicate the immediate usefulness of the generalization $S_m = 20$ to justify the intrapolation of entropies. Another use may be the checking of melting points where their determination presents experimental difficulties.

The Entropy of Fusion

The question of the entropy of fusion (S_f), or as it has usually been stated the constancy of AL/T_m (A —atom. weight, L latent heat of fusion) has been a matter of controversy since H. Crompton,¹ although the latter ex-

¹ For a recent discussion of the rule see A. Jouniaux: Bull., (4) 37, 513 (1925).

pression has been occasionally used, so for instance by Born to evaluate ΔL from the melting point of carbon. The experimental data although very rough cast a doubt on this relation.

Our previously developed statement that $S_m = 20$ does not give a possibility to answer definitely this question, because the small value of S_l which varies between 1 and 3 entropy units is too small in comparison with the value of 20 for S_m , but several cases show that the differences of S_l and S_m compensate when we add both values. We shall therefore propose as a rule that the entropies of all elements, which do not undergo marked chemical changes are equal to 22 entropy units in the fused state at their melting points. We shall therefore call the melting point a corresponding state for the entropies.

The Entropies at the Critical Point

It is a consequence of the above statement to inquire into the question of the entropies at the critical temperature. Unfortunately we have no experimental data for the direct solution of this question. For the sake of orientation we will assume the empirical rule that $T_k = 1.55 T_{\text{boil } p}$. The entropy at the critical point will be

$$\int_0^k c_p d \ln T = S_L + 2.303 c_p \log T_k/T_m$$

$$= 22 + 0.44 c_p + 2.303 c_p \log T_B/T_m$$

It has been noticed during the course of the investigation that the value of $\log T_B/T_m$ is the same periodic function of the atomic weight as in the case of S_{298} (Fig. 1). To arrive at a constant value of S_k we have to expect that c_p of the liquid will also be a periodic function of the atomic weight but with the inverted character. The few data available seem to support this assumption. In fact for K, Rb, and Cs with practically equal $\log T_B/T_m$ the atomic heat is also very nearly equal to 7.5. For Br which has a very low $\log T_B/T_m$ this value is 8.6 in support of our expectations. There is the further evidence in favour of our assumption: the fairly reliable data on the heats of evaporation show the same periodic regularities as do the atomic heats of the liquid elements.

These facts would indicate the possibility of the critical temperature being a corresponding state for entropies. An idea about its numerical value we can find by calculating it for one substance e. g. Na or K where the data are best. To avoid great uncertainty in evaluating c_p for liquids at very high temperatures we will use the safer way and base our considerations on the empirical fact that the plot of the $\ln p$ against $1/T$ is always a straight line, consequently the heat of evaporation will be the same as experimentally determined at lower temperature. Now the liquid will have to gain the entropy of evaporation plus the entropy of a gas i. e. $5 \ln T_k/T_m$ to have the same entropy as a gas at the critical point. It is easy to see that the latter quantity, unless T_k/T_B largely differs from the empirically known value of 1.55 will not vary much from 7 entropy units. On the other hand the entropies of evaporation

of Na, K, Rb, Cs and very many other metals are close to 20, which gives a total for $S_k - S_L = 27$. It must be kept in mind however that the conclusions on critical temperatures will concern metals only.

We can thus tentatively generalize our observations:

The entropies of elements are equal at the following corresponding temperatures¹

$$\begin{aligned} &\text{at } 0^\circ\text{K} \quad (S_0 = 0) \\ &\text{at } T, \text{ where } c_v = 3/2R \quad (S_0 = 1.62) \\ &\text{at the Mp., for the liquid } (S_L = 22) \\ &\text{at the Crit. point } (S_k = 49) \end{aligned}$$

The known relations concerning the entropies of elements do not seem to interfere with our rule.

The entropy of a monatomic gas is $S = 5/2R \ln T - R \ln p + S_0$, where S_0 has been proved by quantum theory considerations to be a function of the atomic weight (M). Since the function f in $T_k^{5/2} p_k = f(M)$ is unknown there is no objection to $S_k = F(M) = \text{const.}$

The same concerns Eastman's² relation

$$S = 3/2R \ln M + R \ln \beta^{3/2}/v + C$$

where f for $\beta^{3/2}/v = f(M)$ is not known.

Summary

Experimental data are tabulated for a large number of elements to show that their entropy at the melting point is 22 entropy units for the liquid phase.

The term corresponding temperatures for entropies is introduced and tentatively extended to the critical temperature.

*Physical Chemistry Laboratory
University of Latvia, Riga.
January 5, 1927.*

¹ Lewis and Gibson (J. Am. Chem. Soc., 39, 2560 (1917)) have demonstrated that at temperatures, where the value of $c_v < 6$, the entropies of solids are equal at temperatures where the c_v values are equal. This is undoubtedly true for $c_v = 3R/2$ because in this region there is no appreciable difference in c_v and c_p .

ADSORPTION BY METALLIC HYDROXIDES. PART III. ADSORPTION BY PRECIPITATED ALUMINIUM HYDROXIDE

BY KSHITISH CHANDRA SEN

In previous papers, I have studied exhaustively the behaviour of hydrous ferric oxide as an adsorbent. In the following pages, the experimental results with hydrous aluminium oxide are given.

Adsorption of Arsenious Acid

The adsorption of arsenious acid by hydrated alumina has been studied by Lockemann and Paucke¹, who have shown that arsenic, in the form of arsenite or arsenate is completely removed from a dilute solution by aluminium hydroxide at the temperature of the water bath (80-90°), but not at room temperature. When the aluminium hydroxide was precipitated at higher temperature in presence of arsenite, more adsorption was noticed than when it was precipitated in the cold, the apparent explanation being due to the difference in the nature of the precipitate formed at the two temperatures. Lockemann and Paucke were however interested in the complete separation of arsenic, and they did not carry out their experiments in details. Further, in their experiments, considerable quantities of other electrolytes were present, and hence it was thought desirable to obtain some quantitative data with freshly prepared and well washed hydrated alumina. While the manuscript of this paper was being prepared Yoe² published an article in which some experiments on the adsorption of arsenious acid by precipitated alumina have been made. As my experiments are however more exhaustive and differ in some respects, the full results are therefore given.

TABLE I

Adsorption of arsenious acid.

$\text{Al}_2\text{O}_3 = 0.2670 \text{ gr.}$

Vol. = 100 cc.

Time = 20 hours; $\text{KCl} = 0.05 \text{ mole per litre}$

	Conc. of As_2O_3 in terms of iodine N/18.65	Adsorption in terms of iodine
(1)	185.75 cc	23.25 cc
(2)	185.75 cc	23.25 cc
(3)	148.6 cc	21.1 cc
(4)	148.6 cc	21.1 cc
(5)	111.45 cc	18.45 cc
(6)	111.45 cc	18.45 cc

¹ Lockemann and Paucke: *Kolloid-Z.*, **8**, 273 (1911).

² *J. Am. Chem. Soc.*, **46**, 2390 (1924).

The experimental method employed is the same as in the case of ferric hydroxide. The alumina was precipitated in the cold from a two-normal solution of aluminium chloride by a slight excess of ammonia. The sample was partly washed by decantation, and then completely by dialysis. The same sample has been used in all the experiments given below. In order to eliminate the effect of ageing, the sample has been used after 25 days after preparation. The oxide was always kept under water.

The data in Table I were obtained to study the reproducibility of the results.

These results show that in duplicate measurements, the same values of adsorption were obtained. At this place, the effect of KCl on the final equilibrium was investigated, but it was found that KCl does not show any effect on the amount of adsorption of acids by hydrated alumina.

Effect of time. The data in Table II show the effect of time on the adsorption equilibrium.

TABLE II

Conc. of As_2O_3 in grms.	Amount adsorbed after 20 hours	Amount adsorbed after 48 hours
0.39424	0.05598	0.05598
0.29568	0.04894	0.04894

From these results, it is evident that the equilibrium has been reached within 20 hours. Yoe (loc. cit.) however found that there is a further change in the amount of adsorption after 72 hours, but he considers that this change is due to some other cause.

In Table III the results obtained with varying concentration of the arsenious acid with a fixed amount of alumina are shown.

TABLE III

Original conc. of As_2O_3 in grams	Conc. of the solution after adsorption	Adsorption in grms per gram adsorbent
0.49280	0.43110	0.2311
0.39424	0.33826	0.2096
0.29568	0.24674	0.1833
0.19712	0.15520	0.1570
0.09856	0.06899	0.1108

Effect of temperature on the adsorptive power of alumina.

The effect of heating the sample of alumina on its adsorptive power was investigated by taking 10 cc of the alumina suspension in the experimental flask, and keeping the flask in boiling water for 15 minutes. The flask was then cooled to the laboratory temperature, and the amount of adsorption of the arsenious acid was investigated in the usual way. In Table IV the results are shown.

TABLE IV

Original conc. of As_2O_3 in grms	Amount of adsorption alumina—not heated	Amount of adsorption with heated alumina
0.39424	0.05598	0.04669
0.29568	0.04894	0.03967
0.19712	0.04192	0.03130
0.09856	0.02957	0.02162

It will be thus observed that the amount of adsorption decreases appreciably when the alumina is heated before the experiment is made. The effect of heating is doubtless to change the physical nature of the precipitate.

Effect of volume—when the concentration of the arsenious acid in terms of normality is constant. The actual amount of solute is thus different, Table V.

TABLE V

Concentration of As_2O_3 = 0.19712 grm. per 100 cc.

Wt. of Al_2O_3 = 0.2670 grams.

Volume of solution	Amount adsorbed in grms
60 cc	0.03877
70 cc	0.03956
80 cc	0.04059
90 cc	0.04130
100 cc	0.04192

Effect of volume. When the amount of solute is the same in every case. The concentration in terms of normality is thus different in each case, and the sample of alumina was an old one, Table VI.

TABLE VI

Concentration of As_2O_3 = 0.2278 gr.

Wt. of Al_2O_3 = 0.2670 grams.

Volume of solution in cc	Amount adsorbed in grms
100	0.02673
90	0.02740
80	0.02808
70	0.02943
60	0.03024

From Tables V-VI it will be observed that the volume of the solution has a great effect on the actual amount of adsorption by a given weight of the adsorbent. When the normality of the acid is the same, the amount of adsorption increases with the increase in the volume of the solution, and if the amount of the solute is constant, the less the volume of the solution the greater is the amount of adsorption. These results are therefore quite similar to those obtained with ferric hydroxide and given in Tables XIV to XVIII in part I of this series of papers.

Effect of some non-electrolytes like sugar and alcohol which usually decrease the surface tension of water was also investigated. The results obtained however showed that with moderate addition of either cane sugar or alcohol, there was no change in the amount of adsorption.

In Table VII the *effect of varying the quantity of the adsorbent* on the amount of adsorption of arsenious acid is shown.

TABLE VII
Conc. of As_2O_3 = 0.19712 gr.

Amount of adsorbent in grms	Conc. of solution after adsorption	Amount adsorbed per gram adsorbent
0.2136	0.16317	0.1590
0.2670	0.15520	0.1570
0.3738	0.14326	0.1441
0.4806	0.13001	0.1396
0.6408	0.11409	0.1296
0.7476	0.10480	0.1235

Reversibility of Equilibrium.

In order to test whether the adsorption of arsenious acid by hydrated alumina is reversible or not, two sets of experiments were tried. In one set, 0.2670 gram of Al_2O_3 was treated with 50 cc of N/25.11 As_2O_3 solution and kept for 20 hours. Then 50 cc more of water was added, the mixture shaken and allowed to settle for another 20 hours. At the end of this period, the supernatant liquid was analysed. In an exactly similar experiment, the alumina was treated with 100 cc of N/50.22 As_2O_3 solution. The final concentration of the supernatant solution in both the cases was found to be N/70.41. In another set, proceeding in the same way, 50 cc of a solution of As_2O_3 N/12.55 was added, and after 20 hours another 50 cc of water. In another flask, 100 cc of N/25.1 As_2O_3 solution was added at the same time. After analysis, the concentration of the supernatant liquid in both the cases was found to be N/31.7. It was thus clear that the adsorption equilibrium in this case was perfectly reversible.

Up to this time, the adsorption of arsenious acid by hydrated alumina has been investigated. It became here a matter of interest to study the adsorption of sodium arsenite by hydrated alumina and to compare the relative adsorbability of the two substances. In Table VIII, the results obtained with sodium arsenite are shown.

TABLE VIII
Wt. of Al_2O_3 = 0.2670 gr.

Original conc. of Na arsenite in terms of $\frac{1}{2}$ N/18.65	Amount adsorbed in terms of $\frac{1}{2}$ N/18.65
148.6 cc	21.1 cc
111.45 cc	18.45 cc
74.3 cc	18.8 cc
53.7 cc	13.7 cc
37.15 cc	11.15 cc

The adsorption values have been given in terms of iodine because it was found that mainly the arsenite ion was adsorbed. In Table IX a comparative study was made of the amounts of adsorption of As_2O_3 and sodium arsenite when the original concentrations in terms of iodine are the same.

TABLE IX

Original conc. in terms of iodine N/18.65	Adsorption of As_2O_3	Adsorption of Sodium arsenite
148.6 cc	21.1 cc	21.1 cc
111.45 cc	18.45 cc	18.45 cc
74.3 cc	15.8 cc	15.8 cc
37.15 cc	11.15 cc	11.15 cc

These experimental results therefore show that with both these substances, it is the arsenite ion which is actually adsorbed and from equivalent solutions, the amount of adsorption in terms of iodine is the same. The result is therefore different from that obtained with ferric hydroxide.

Having thus studied the adsorption of arsenious acid under various change of conditions, the adsorption of other mineral and organic acids by the same sample of hydrated alumina was investigated, Tables X-XV. The concentration of the acids has been varied as was done in the case of experiments with hydrous ferric oxide. Several acids like hydrochloric, acetic, propionic, butyric, etc., could not be used owing to their great peptising power, and hence the choice of acids used in this investigation is somewhat limited.

Wt. of Al_2O_3 used = 0.2670

Volume = 100 cc

Time = 20 hours, KCl = 0.05 mole per litre.

0.2277	0.0099	0.8158

TABLE XV
Comparative adsorption of some acids when the initial concentration
is the same

Conc. of acid = 1.1320 milliequivalent per 100 cc.

Wt. of Al_2O_3 used = 0.2670 gr.

Acid	Adsorption per gram adsorbent.	Acid	Adsorption per gram adsorbent
Citric	2.3490	Malic	1.7180
Racemic	1.9040	Hippuric	1.2740
Oxalic	1.8660	Succinic	1.2740
Sulphuric	1.7930	Benzoic	0.7543

So far, the results obtained in the adsorption of acids by alumina has been given. It has however been shown that sodium arsenite is also highly adsorbed by alumina and the amount of adsorption expressed in terms of iodine is the same for both the arsenite and pure arsenious acid. In this connection the adsorption of some other salts and alkali has been investigated. In the case of salts like sodium phosphate, sodium citrate, etc., usually the negative ion is preferentially adsorbed when the solutions of these salts are shaken with freshly precipitated alumina. This change is noticeable by adding to

the solution some phenolphthalein when the pink colour is obtained. Quantitative results were however difficult to obtain owing to the smallness of the value of adsorption.

The amount of adsorption of alkali by alumina is however quite appreciable, and has been investigated in the usual way. In Table XVI, the results are shown. The amount of alumina is the same as used in the experiments with acids, and other conditions also remain the same.

TABLE XVI
Adsorption of Caustic Soda

Original conc. milliequivalents	Conc. of solution after adsorption	Adsorption per gram adsorbent
1.1320	0.7999	1.244
0.9909	0.8608	1.161
0.7921	0.4960	1.109
0.5940	0.3179	1.034
0.3960	0.1399	0.959

From these results it is obvious that the adsorption of alkali by alumina is fairly great, and in some cases comes to about 25 per cent of the total amount. Alumina, therefore, adsorbs not only acids, but also bases to a considerable extent.

THE IONISATION OBTAINED BY BUBBLING AIR THROUGH VARIOUS SOLUTIONS

BY CHARLES R. PITTS

It is commonly known that, when air is bubbled through a liquid, electrical charges of both signs are carried along with it, one of which is in excess of the other in most cases. At the outset of this paper I would like to go over, in some degree, the historical background of the ionisation produced by bubbling air through liquids.

Lenard¹ investigated the well-known fact that there is something exceptional taking place in the phenomena of atmospheric electricity at the foot of a waterfall, when the water falls upon the rocks and breaks into a spray. The splashing of rain changes the atmospheric electrification; it electrifies the air negatively. Lord Kelvin² found that when air is bubbled through water there was a negative charge carried along with it; but when air was caused to bubble with great vigor the air carried along with it both positive and negative ions, though the latter were the more numerous; air treated in this way was found to discharge a body with a negative charge, though not so rapidly as one with a positive charge. He also found that with the addition of salts and acids to the water the effect was diminished, and in some cases the sign of the total electrification was reversed.

Kösters³ found that while air is bubbled through pure water it was negatively charged, but with the addition of .007% of sulphuric acid to the water the air came through electrically neutral and with the addition of more acid the charge was positive.

De Broglie⁴ varied the investigation by splashing or breaking up of the drops of water in air and called his experiment, "Ionisation by Bubbling" (*barbotage*). He showed that the intensity of ionisation obtained by the splashing of drops produced by forcing a liquid through an orifice on to a plane surface depended greatly on the diameter of the orifice. It was weak for capillary tubes and then passed to a maximum and again became weak for large diameters.

Among those who have investigated the ionisation produced by the bubbling of air through liquids are: Lord Kelvin, Maclean,⁵ Kösters, MacTaggart⁶, and de Broglie.

All these experiments show that the change in area of a liquid surface in contact with a gas gives rise to an electrification of the gas.

⁵ Phil. Trans., 191A, 187 (1898).

⁶ Phil. Mag., (6) 27, 297; 28, 367 (1914).

It was shown by Holmgren¹ that when the surface of water was changing rapidly, for example, when ripples were travelling over the surface, or when two wet cloths are brought together and then suddenly pulled apart, electrification was produced, the negative in each case being in the air.

Evaporation of the liquid will not carry away a charge unless it is attended by agitation. It may be easily shown that if the vapor escaping from a charged surface of water carries with it any charge it must be very small. Many experimenters have failed to observe any loss from a liquid due to its evaporation. Pellat,² in his experiments on this subject made observations extending over an hour and then was able to detect only a very small loss from a large surface of water, and with a very sensitive apparatus.

It has long been recognized, largely on account of the properties of the capillary electrometer, and the electrical effects obtained with the bubbling of gases through liquids, that the surface of a solution, and the interfacial surfaces of a solution in contact with a metal or another solution might be the seat of an electrical segregation resembling a charged condenser. The condition of the formation and existence of these double layers have been investigated mathematically by Kleeman³, and made the basis of a theory of the voltaic cell. The segregation of electricity arises, it might be pointed out, through the transition layer changing in density from one side to the other, and in which the ions of different signs therefore have different values for the coefficient of diffusion and mobility. This gives rise to a distribution of ions so that on passing from one side of this transition layer to the other, at first ions of one sign are in surplus, which increases and then decreases to zero, and which is followed by a surplus of ions of the other sign which also passes through a maximum. Thus in a solution the number of ions of one charge predominate in number over the ions of opposite charge near a metal surface or at the surface of the liquid.

Experiments to determine the electrical nature of the layer furthest from the surface have been carried out by Kleeman and the writer.⁴ It is highly probable that this layer has something to do with the electrification produced by bubbling.

When the bubbles explode at the top of the liquid there is a certain decrease in the surface, which must be attended by some electrical rearrangement that might conceivably have an effect on the adjacent gas. Possibly absorbed air in the ionized condition in the layer is expelled.

In looking through the literature on the experiments by the above-named men in no place has there been found an extensive investigation including the common soluble salts. It was the intention in this investigation to cover the field more fully than heretofore; to determine the relative amount of ions of both signs and to determine the charge excess liberated when air is bubbled through every aqueous solution obtainable.

³ Phys. Rev., (2) 20, 174 (1922).

⁴ Kleeman and Pitts: J. Phys. Chem., 29, 508 (1925).

The experiments were carried out by means of an apparatus shown diagrammatically in Fig. 1. A glass tube (4) about 6 cm. in diameter and 50 cm. long was clamped with its axis vertical in a stand. The lower end of this tube was closed by a stopper, through which passed a glass tube of about 15 mm in diameter, which had a force pump attached to its lower end. Over the upper end a common baby nipple (2) was tied to the glass tube. This nipple was pierced at a number of places by a thin sewing needle. Hence, when the tube (4) contained a solution and the pump was operated, small bubbles of air was formed on the surface of the rubber nipple and rose to the surface of the solution, the size of the bubbles depending on the pressure of the air from the pump. This pressure could be regulated at will by means of a suitable attachment.

This force pump was an electrically-driven blower and vacuum pump, the type used for producing a blast for the operation of blast lamps, and for use requiring moderate air pressure and vacuum. The outer casing of the blower is water-jacketed so that the heat developed during continuous use may be removed.

Resting on the top of the glass tube was a copper cylinder (5) which is about 20 centimeters long. Number (7) represents a bank of B-batteries of 180 volts connected through a reversing key to this copper cylinder (5). Number (6) represents an electrode, which was centrally located inside of the copper cylinder (5). This electrode was connected directly to a quadrant electrometer through the short-circuiting switch (9) or earthing key of special construction. A copper rod, having one end connected to earth and the other end dipped into a brass vessel containing a solution of calcium chloride, passes through an earthed metal tube. A conducting wire, which is attached to the quadrants of the electrometer, is attached to the earthing key by means of a terminal. On raising the rod (9) the quadrants are insulated, and, when bubbling is taking place, a current begins to flow from this electrode to the

electrometer. The key and its connections are enclosed in a metallic case and connected to ground to protect them from electrostatic disturbances. The key is raised and lowered by means of a string passing out of the metallic case over a pulley.

In making measurements of these ionisation currents, the electrometer and all of its connections were enclosed in metallic conductors connected to ground for shielding purposes. The wire leading to the electrometer was passed through a brass pipe supported at each end by ebonite plugs. All ground connections were to water pipes and great care was taken to insure good contact by soldering.

negative ions liberated to the electrode, this giving the electrometer a minus charge.

In each case the natural leak was taken with the polarizing battery on but with no bubbling. The grounding key (9) was removed and the electrometer deflection was noted over a period of several minutes, the polarity of the copper cylinder was then reversed and the natural leak was taken corresponding to the opposite sign. This natural leak, in the majority of cases, was zero, and where it was appreciable it was subtracted from the deflection when bubbling.

In determining this excess of ions liberated I was not particularly interested in any quantitative measurements, but more in the relative number of positive and negative ions liberated when salts were added to distilled water. Thus distilled water was first bubbled over a period of 20 minutes (Curve 1) first measuring the amount of negative ions liberated, then by reversing the polarity of the cylinder (5) measuring the amount of positive ions liberated, over the same period of time, and with the same amount of bubbling, thus the relative number of ions liberated could be determined by comparing the deflections of the galvanometer.

As stated above, when air is caused to bubble vigorously through distilled water, both positive and negative ions are liberated; but the negative ions are liberated in excess. In order to determine the relative number of positive and negative ions liberated the copper cylinder (5) was placed on the glass cylinder (4) and kept, when bubbling, at potential of plus or minus 180 volts by means of the reversing switch. When this copper cylinder is positive, it will attract the negative ions liberated and repel the positive ions liberated to the electrode and thus charge up the electrometer positively. On reversing the polarity of this copper cylinder it would attract the positive ions liberated and repel the

Distilled water was tried several times and it was found that the number of negative ions liberated was approximately 2 to 1 over the number of positive ions liberated. This was checked several times and this result was obtained each time within the range of experimental error.

Curve 1 shows the relative amounts of positive and negative ions liberated with time when air is bubbled through distilled water. The ordinates represent the scale deflections in centimeters and the abscissae represent the time of bubbling in minutes. The upper line represents the deflection when the electrometer is being charged negatively and the lower line represents the deflection when the electrometer is being charged positively. Thus the ratio $+/-$ can be determined by dividing the positive deflection over any period of time by its corresponding negative deflection. Both of these lines show that the amount of positive and negative ions liberated under these conditions is practically a straight line relation. It has been stated in the first part of this paper that negative ions are liberated in excess, and these curves show conclusively that this is correct.

Table I shows the ratio of the number of positive ions to the number of negative liberated in the case of salt solutions, namely, $+/-$. The deflection

was noted over a period of two minutes, then the polarity of the copper cylinder (5) was reversed and the deflection corresponding to the opposite sign over the same length of time and with the same amount of bubbling was noted. This was done four times for each sign and the ratio of the means was taken. There is considerable error in an experiment of this kind, but these results agree within 10%. In the case of each solution tried the ratio of the $+/-$ is increased from what was obtained with distilled water.

Table II shows the ratio of the number of positive ions liberated to the number of negative ions liberated, namely $+/-$, when air is bubbled through these solutions. The deflection was noted over a period of 10 minutes instead of 2 minutes as before, then the polarity of the copper cylinder was

Note: The above ratios ($+/-$) were obtained for bubbling over a period of 10 minutes.

reversed and the deflection corresponding to the opposite sign over the same length of time and with the same amount of bubbling was noted.

This ratio seems to depend to a slight extent, upon the time of bubbling as will be found on comparing the ratio \pm for solutions common to the Tables I and II. In most cases it increased but it was difficult to repeat these values because it probably depends upon the amount of absorbed air. If it does depend upon the amount of absorbed air, it would thus depend upon the previous treatment of the solution.

The ratio \pm depends on the concentration. The effect of concentration in the case of aqueous solutions of NaCl was accordingly studied.

5%	3.68
10%	4.46
15%	2.64
20%	2.93
25%	1.67

Note: The above ratios (\pm) were obtained for bubbling over a period of 10 minutes.

In studying the relative amounts of positive and negative ions liberated with concentration (mol fraction) of solution the following concentrations of NaCl and distilled water were used: 1/4%, 1/2%, 1%, 3%, 5%, 10%, 15%, 20%, and 25%. On Curve 2 the ordinates are the ratios of \pm and the abscissae are the concentrations of the solutions. At zero concentration or distilled water the minus is liberated in excess thus the ratio resulting in a decimal, but with the addition of more salt the ratio becomes larger, showing that the positive are now liberated in excess, and at higher concentrations the ratio steadily decreases thus showing that the minus are again being liberated in excess. Some important deductions can be made from this curve, namely,

by tracing along this curve we can find points where it crosses the line where the ratio $+/-$ equal 1, determining the amount of salt which is necessary to make an aqueous NaCl solution electrically neutral. This is similar to the work which Kösters did, as already referred to in bubbling sulphuric acid.

It may be noted from Curve 2 that for lower concentrations ($\frac{1}{4}\%$, $\frac{1}{2}\%$, 1% and 3%) the value of $+/-$ does not vary very much. Beyond the 3% solution its value increases rapidly to a maximum and for high concentration decreases and becomes nearly unity again. Thus we are led to believe that the ratio $+/-$ in the case of an aqueous solution of NaCl in general decreases, increases, and then decreases.

It is likely that the other solutions show a similar behaviour with change in concentration. A line of further and important research is thus suggested.

I desire to express my thanks to Dr. Kleeman for suggesting this research and for helpful suggestions in carrying it out. I wish to express my appreciation to the General Electric Company and to the Chemistry Department at Union College for their assistance in obtaining chemicals used in this investigation.

THE POSITIONS OF THE K-ABSORPTION LIMITS OF VANADIUM IN VARIOUS OF ITS COMPOUNDS

BY STERLING B. HENDRICKS AND RALPH W. G. WYCKOFF

Introduction

Recent experiments have shown that the positions of the X-ray absorption limits of an element depend upon the state of its chemical combination. Early measurements of this character indicated¹ that the K-absorption limit from white phosphorus occurs at a slightly different wave length from the limit for red phosphorus. From subsequent observations,² for the most part upon compounds of phosphorus, chlorine and sulfur, it is clear that the valence of an element is an essential factor in determining shifts in its absorption edge. Existing data are nevertheless sufficient to show that other influences, not thoroughly evaluated, have important bearings upon these phenomena. The results of this paper, upon compounds of vanadium, are the first of a series of absorption measurements which it is hoped will eventually provide data necessary for an understanding of the phenomena of absorption. Since they appear to form some sort of a measure of the effects of chemical changes upon atomic structure, their systematic investigation is of both chemical and physical interest. The absorption edges of vanadium compounds are comparatively easy to measure because, though this K-absorption limit falls within a region where the magnitude of the wave length shift far exceeds the error involved in its measurement, such X-rays are not so soft that the experimental manipulation becomes difficult.

The Method of Experimentation and the Accuracy of the Results

For wave lengths shorter than 1.0\AA shifts in absorption limits are of the same order of magnitude as the errors inherent in the most accurate measurements of X-ray wave lengths. Even though they are increasingly significant at longer wave lengths, their careful study requires that methods of precision spectrometry always be employed.

A Siegbahn vacuum spectrograph³ of the usual type has been employed. In this instrument the crystal-to-plate distance is approximately equal to the crystal-to-slit distance. All photographs have therefore been made with a stationary crystal. The slit, 0.1mm. wide, was covered with a thin film of collodion. The measured spectra were either second or fourth order reflections from (100) of calcite. The spacing of this second order reflection⁴ has been taken to be 3020.04 X. U.

⁴ Siegbahn: *ibid.*, p. 84.

Two entirely different sets of experiments were carried out, using different targets as sources of X-rays and different calcite crystals as gratings. In the first group, upon V_2O_5 and NH_4VO_3 , the water-cooled metal tube had a platinum anticathode. The crystal-to-plate distance for these experiments was accurately determined by measuring, upon a series of second order Cu-K spectra, the separation of the lines Cu- $K\alpha_2$ and Cu- $K\beta_1$. The accepted wave lengths¹ have been used for these and all other emission lines. Wave length measurements upon the vanadium absorption limits were then obtained from separations measured between these edges and the fourth order Pt-L β_1 line always occurring upon the plates. In a second and more numerous group of experiments, upon V_2O_5 and NH_4VO_3 as well as upon all the other vanadium compounds subsequently to be mentioned, a tube with a thorium target was employed. Standard emission lines of a suitable wave length arose from placing a small quantity of metallic chromium upon this anticathode. The crystal-to-plate distance was deduced from a series of measured separations between Cr- $K\alpha_2$ and Cr- $K\beta_1$. The standard emission lines from which the wave lengths of the absorption edges were directly calculated were either Cr- $K\alpha_2$ or Cr- $K\alpha_3$. In all these experiments the X-ray tube was operated at a peak voltage of from 8000V to 10000V with a current of 30-35MA. Two hour exposures furnished good photographs.

The compound to be examined was prepared by grinding a small weighed quantity with a known volume of celluloid dissolved in amyl acetate. This suspension was poured upon a given area of glass plate and allowed to harden. The resulting film, after being blackened with india ink, was placed between the slit and the crystal. Liquids were mounted in the same manner. Certain compounds of vanadium, however, react with the amyl acetate-celluloid solution. In such cases another method was used. The compound was suspended in melted paraffin and allowed to cool. Thin sections were then removed with a razor. A new specimen was always used for each photograph that was made. The samples for the vanadium compounds studied contained from 2 to 10 mgs. per. sq. cm. and were from 0.01 to 0.1 mm. in thickness.

The plates were measured on a comparator having a screw accurate to 0.001 mm. The details of interest on the plates could be measured to about 0.01 mm. Both visual and photometric observations have been carried out. Under existing experimental conditions the visual measurements (using magnification of ca 3X) proved to yield the more significant and reproducible results. They have therefore served as the basis for all of the data recorded in this paper.

Some of the present measurements are lower than previous ones² on salts of vanadium by an amount which exceeds the probable error. (See Table I). In such instances both Pt-L β_1 (2) and Cr- $K\alpha_3$ were used as reference lines. The former of these is on the short wave length, the latter on the long wave length, side of the edge. The fact that both sets of the present results agree within

the limit of accuracy indicates that all of the data of this paper are precisely comparable amongst themselves. Since the shape of a photometered curve is a function of such factors as the width of the photometer slit, it is possible that the divergence of the earlier results may arise from the selection of different features of the absorption.

In both the emission photographs made for purposes of standardization and in the absorption photographs, each plate was measured five times in either two or three separate positions. The final result is thus an average of from ten to fifteen distinct measurements. Representative data from a typical photograph are recorded in Table II. Four separate photographs were usually made from each compound.

Absorption edge	2.035	2.045	2.040	2.032

Preparation of the Compounds

Although no great effort was made to prepare pure compounds, care was taken adequately to identify the preparations used. Criteria for this purpose were either a determination of the vanadium content or else some characteristic reactions and physical properties. Attention was at all times given to the possibility of decomposition of the compound under the action of the X-rays.

All analyses were made through SO₂ reductions of the vanadium compound in H₂SO₄ solution to the vanadyl state. The excess SO₂ was removed by CO₂ and the hot solution titrated with KMnO₄ (ca N/20). Objectionable acids were first removed by evaporating with H₂SO₄. Lower valence compounds were at the outset oxidized with HNO₃ or H₂O₂—the excess of oxidizing agent being later destroyed.

Absorption measurements have been made upon the following preparations.

- V₂O₅ (a) Commercial (Red). 49.80% V. (calc. for V₂O₅, V = 56.04%)
(b) Yellow (Kahlbaum product).

V_2O_4 , V_2O_5 Measurements were made upon samples supplied by Prof. L. M. Dennis of Cornell University.

VO— $V(OH)_2$ ¹ Brownish purple $V(OH)_2$, obtained by adding an excess of NH_4OH to a solution of a vanadous salt, was dried in a current of oxygen-free CO_2 and later heated to a red heat. This material showed the characteristic reactions of vanadous salts—it decomposed acids with an evolution of hydrogen, thus furnishing an acid solution which had the green color of a vanadic salt. Analysis gave the following result: 64.0% V (calc. for VO 76.11% V; calc. for $V(OH)_2$ 60.00% V).

V Measurements were carried out upon a chemically pure product supplied by Dr. Jordan of the Bureau of Standards.

K_3VO_4 A melt² of one mol of V_2O_5 and three mols of anhydrous K_2CO_3 was held liquid at 1000°C for several hours. The product contained a slight excess of carbonate.

Na_3VO_4 The method of preparation resembled that used for K_3VO_4 . One mol of V_2O_5 was fused with three mols of $Na_2CO_3 \cdot H_2O$.

NH_4VO_3 Kahlbaum. 43.48% V (calc. for NH_4VO_3 , V 43.59%).

$K_4V_2O_7$ The method of preparation was the same as that used for K_3VO_4 except that one mol of V_2O_5 was fused with two mols of K_2CO_3 . In these fusions, a large excess of either of the reacting substances was required to be absent.

Na_3VS_3O By passing³ dry H_2S over Na_3VO_4 at a red heat, Na_3VS_3O was obtained as a red brown crystalline powder melting without change to a purple liquid.

V_2S_3 Commercial⁴ V_2O_5 (containing 49.80% V), heated to redness in a current of CS_2 gave V_2S_3 as a graphitic black powder. Analysis: 46.40% V (calc. for V_2S_3 , 51.51% V).

V_2S_5 V_2S_3 and a large excess⁵ of sulfur were heated to 500°C in a closed tube.

$VOCl_3$ V_2O_5 mixed⁶ with P_2O_5 was treated at 80°C with dry HCl . The resulting clear yellowish-red liquid was redistilled without exposure to the air. This $VOCl_3$ forms with amyl acetate-celluloid a dark red solution. It also dissolves in paraffin giving it a similar dark red color. Both preparations yielded the same edge.

VOCl Employing a stream of dry hydrogen, freshly⁷ prepared $VOCl_3$ was distilled into a tube having a small portion of its length heated to bright redness. Light brown $VOCl$ deposited beyond this heated portion.

VCl_4 , VCl_3 Dry chlorine was passed over well powdered ferro-vanadium with the formation of VCl_3 , $FeCl_3$, and VCl_4 . The more volatile VCl_4 was separated by several distillations as a dark reddish brown liquid. Purple

crystals of VCl_3 were deposited in the VCl_4 containers. By following this procedure contamination by oxychlorides is prevented. Both halides were mounted in melted paraffin. Unless the temperature is maintained as low as possible, VCl_4 reacts with the paraffin giving copious fumes of HCl .

NH_4VO_4 A saturated¹ aqueous H_2O_2 solution of NH_4VO_3 was treated with alcohol. The yellow powder precipitating out was washed with ether and dried in air. Analysis: 37.27% V (calc. for NH_4VO_3 , 38.34% V). It is probable that NH_4VO_4 decomposed under the conditions of these experiments.

Experimental Results

Data from the vanadium compounds examined are listed in Table III. In agreement with previous results some of the plates showed near the absorption edge a white line, similar in appearance to a reversed emission line. Because its long wave length edge coincides with the absorption edge of metallic vanadium, this white line has been supposed² to arise from reduction to the metal of vanadium in the samples. It seems hard to reconcile this explanation with the relative chemical stabilities of the vanadium compounds which have been investigated. The experiments recorded in this paper do not satisfactorily establish the source of this phenomenon. It is therefore felt that its more detailed discussion may profitably await further experimental results.

The effect of valence upon the absorption edges of the compounds of Table III is made evident by Table IV. Absorption edges from pentavalent vanadium have the lowest wave lengths. Taken as a whole the compounds with lower valence yield absorption edges which are at longer wave lengths the lower the valence. Nevertheless compounds of a single valence type show pronounced variations among themselves and it sometimes happens that compounds of one valence group overlap those of adjacent groups. Chlorides and oxychlorides give longer wave length edges than the corresponding sulfides and oxides. If compounds of the same chemical sort are compared (Table V), the increase of wave length with decrease in valence is more regular.

Comparisons between the pentavalent compounds of vanadium bring out several interesting facts (Table VI). The two binary compounds V_2O_5 and V_2S_5 give much shorter edges than any others except NH_4VO_3 . Pyro- and ortho-vanadates are similar but their edges differ markedly from that of the meta-vanadate that was studied. The edge for Na_3VO_4 is appreciably different from that for the corresponding potassium salt. It is of interest to observe that the substitution of sulfur for oxygen in these compounds produces only slight absorption edge changes.

It is easy to understand qualitatively why a shift occurs in the X-ray absorption edge when the chemical valence of an atom changes. Apparently conclusive reasons exist for the belief that an increase in positive valence corresponds to a decrease in the number of electrons surrounding an atom.

With this decrease in the number of associated electrons the intensity of bonding of any electron by the nucleus becomes greater. It is a consequence of such an increase in the "effective nuclear charge" that more energy will be required to eject an electron from any energy level in the atom. In terms of such pictures as can now be formed concerning the mechanism underlying the production of X-ray absorption limits, this would result in a shift of these limits towards shorter wave lengths. Though a qualitative explanation of this character may well be correct, its quantitative aspects must be much more complex.

Probably the most important problem now facing valence theory is the question of the existence of shared electrons. Measurements of absorption edges furnish an experimental way of evaluating the effect of chemical combination upon atomic structure. As such they may perhaps be made to tell whether, as a result of the chemical union between a strongly electropositive and a strongly electronegative atom, electrons are completely transferred from one atom to the other. The variations already found in edges from atoms in the same valence state conclusively show that the positions of these edges depend upon other factors than the numerical value of the valence. Among these influences the following might be expected to be important:

(1) The group opposite in sign to that bearing the atom studied, e.g. Na_3VO_4 , K_3VO_4 ; KCl , $NaCl$.

(2) Different kinds of atoms forming the group which contains the atom, e.g. Na_3VO_4 , Na_3VS_3O , Na_3VS_4 , etc.

(3) The numbers of atoms immediately associated with the atom under investigation, e.g. $NaVO_3$ and Na_3VO_4 .

(4) The physical state of the compound.

(5) Polymorphism, e.g. red and white phosphorus.

(6) The crystal structure of the compound.

(7) Temperature.

An evaluation of these factors is obviously a preliminary to any satisfactory explanation of absorption edges but many additional experimental data are needed to achieve such a result.

Conclusions

Accurate measurements have been made of the K X-ray absorption limits of vanadium in several of its compounds. The nature of the variations observed in these limits are mentioned and possible factors determining them are briefly discussed.

THE ZONE PATTERN FORMED BY SILVER DICHROMATE IN SOLID GELATINE GEL

BY E. RAYMOND RIEGEL AND MELVIN C. REINHARD

Introduction: In the course of further studies of the zone pattern formed by colored salts in solid gels¹, it was found possible to obtain the pattern, free from lines, with silver dichromate, the classical example of rhythmic band formation. The gelatine must be previously washed free of the impurities (chlorides) which form a white salt with silver nitrate. It was found that the chloride impurity in commercial gelatine gives itself with silver nitrate a deposit which forms the zone pattern also. The present work establishes that the substructure due to the impurity must be present if the red bands of the dichromate are to form. This conclusion had been reached before, but the evidence was less definite than in the present case. The previous work is fully reviewed further on. The existence of the substructure, that is the fine lines formed by the white silver salt in commercial gelatine, has been observed several times before; these observations are presented briefly. The previous studies have been either with flat glass plates covered with the gelatine, or in test tubes; and the silver solution has usually been extremely concentrated, (25%); whereas our work is done chiefly with cakes submerged in weak silver solution (1%), and with the soft slices cut from such cakes. The observations of the zone patterns are entirely new. Some experiments relating to the effect of sodium chloride addition on the penetration of the silver salt into the gel were also made (tubes).

Washing the Gelatine: On placing silver nitrate solution over a 4% commercial gelatine gel containing potassium dichromate, the red bands which form are preceded by a white haze, and when the action ceases, the haze extends well beyond the red bands. By washing the gelatine, the impurity causing the haze (sodium or calcium chloride) may be removed; in such a washed gelatine the red bands do not form, but merely an unbroken red zone with no haze detectable (test-tubes); the non-formation of haze or of the red bands is a delicate test of the thoroughness of the washing. This may be done in plain distilled water; 50 grams of commercial gelatine are placed in 4 liters of cold water and left 12 hours in contact with it, with occasional shaking; after that time the water is poured off and a fresh volume added. This is repeated twice more. The gelatine is then poured onto a large Buchner filter and freely washed for 1 hour.

Procedure for the Zone Pattern: A 4% solution of the washed gelatine, to which 0.1 gram of potassium dichromate is added for each 100 cc of solution, is allowed to solidify over night in the ice chest. The solid gel is cut into cubes of 3 to 4 cm at the side, and these are submerged in 1% silver nitrate solution for periods of varying lengths, but usually of 4 hours. On removal, a vertical

¹ Riegel and Widgoff: J. Phys. Chem., 29, 872 (1925).

slice 3 mm thick is cut from the center of the cake; it is found that the inner portion of the gelatine is clear, and that the cleared zone extends to the corners; the deposit is unbroken by lines; no white haze can be found. Two such slices are shown as B in the photograph below.

On adding a small amount of sodium chloride to the washed gelatine solution, and otherwise proceeding exactly as above, the red lines of the silver dichromate reappear, also the white haze. In Fig. 1, C represents such a slice from washed gelatine with sodium chloride addition, while A is the original commercial gelatine (unwashed) for comparison.

FIG. 1

The zone pattern formed by silver dichromate deposited in gelatine; A, original gelatine, showing bands; B, washed gelatine, free from lines, and showing the zone pattern; C, washed gelatine with added sodium chloride, showing the reappearance of the bands.

Examination of C established that the white haze had the fine line structure, although very faint.

Effect of Various Amounts of Sodium Chloride: The addition of sodium chloride to the washed gelatine, followed by the usual procedure, did not always result in the reappearance of the red bands, because the concentration of salts in the gel need not be very high to equal that of the outer salt, 1% AgNO_3 , and prevent the formation of any silver dichromate. The decrease in penetration is well shown in the photograph below of 5 test tubes whose gels contained various amounts of NaCl . Each tube contained 10 cc of a 4% washed gelatine solution, to which 0.01 gram potassium dichromate had also been added; the amounts of NaCl were: a, 0.0015 gram; b, 0.003; c, 0.009; d, 0.018; and e, 0.03. The 5 gels were overlaid at the same moment with 10 cc of 1% silver nitrate, placed in the ice chest for 20 hours and photographed, Fig. 2. The penetration in a is three times deeper than in e, which has 20 times as much NaCl . No rings form in d nor in e; for good ring formation, with a 1% silver nitrate solution, the concentration of NaCl should be below 0.1%. An amount as small as 0.001% NaCl still gives rise to a red band. A deep penetration in e was not likely, for the amount of salt added to the amount of dichromate required almost all of the silver nitrate in the solution, so that the osmotic pressure in the gel would about equal that in the solution.

The deposit in e had some red silver salt when photographed; after 8 days, the deposit was snow white; the solution above the gel had turned yellow, while the other tubes still had colorless solution. The chlorine ion travels

to the reaction zone with great rapidity; some of the dichromate ions also move up however, as indicated by the fading of the gelatine just below the deposit, which fading may be observed in Fig. 2. On standing several days, the residual chloride ions move to the reaction zone and displace the dichromate ion in the more soluble silver dichromate; the second product of this displacement reaction, sodium dichromate, passes into the solution (now nearly water) above the gel, tinting it yellow.

FIG. 2

Silver dichromate deposited in washed gelatine gel to which varying amounts of sodium chloride have been added; the amounts increase from left to right. The penetration decreases with increase in the amount of salt added.

The faded portion of the gel just under the deposit, is not so easily detected in *a*, *b*, and *c*, because the white haze interferes; viewing the tubes with blue light, the middle part of the haze is able to take on the blue tinge, hence it is white and the gel in which it lies is faded; the lower part of the gel has not faded. In the absence of other facts this would be evidence that the white haze formation is independent of the potassium dichromate.

The Zone Pattern formed by the Impurity in Gelatine: If a 4% commercial gelatine gel, without the dichromate addition, is made into cubes and these submerged in 1% silver nitrate, the center of the gel is cleared and the cleared zone extends to the corners; a white deposit, rather weak, is formed, as shown in Fig. 3 (taken against black paper). The zone pattern is well developed. Examination with a hand lens reveals fine lines in the deposit.

Dependence of the Red Silver Dichromate Bands on the Fine Lines of the Substructure: The non-formation of bands in the washed gelatine, and the reappearance of the bands on adding NaCl, prove conclusively that the red bands are dependent upon the fine lines of silver chloride. In the adjoined micro-photographs, Fig. 4, the two structures are shown; the camera was

FIG. 3
The zone pattern formed by the chloride impurity in commercial gelatine with silver nitrate.

FIG. 4
Photomicrographs of the substructure of white lines and of the red bands of silver dichromate in gelatine. Magnification $\times 40$.

moved from a point near the edge of a slice toward the center; the red bands become wider, are spaced wider, and become fainter as the center is approached. The fine hair lines similarly are wider, and become themselves wider and more diffuse, as the center is approached. The fine lines extend much further than the red bands, which is in keeping with the deeper penetration of the white haze in the test-tube experiments. The red bands are very evident, but the fine lines are easily missed, when sought visually, the camera exaggerates their effect, Fig. 4. In taking the micrographs, a wet slice of gelatine, freshly cut, was used; for all the other pictures, fresh wet slices were used; this procedure prevents mistaking a crystallised soluble salt, which might separate out on drying, for a structure which truly exists in the wet gel.

Liesegang¹ first noted the white, very fine lines formed in ordinary gelatine (on treatment with silver solution) and ascribed them to sodium chloride; but considered that the fine lines had no influence on the formation of the red bands.

Fritz Koehler² did extensive work in the study of the substructure, and decided that the fine lines were due to crystals of ammonium nitrate or potassium nitrate, the second product of the Liesegang reaction.

C. A. Schleussner³ threw doubt on some of the evidence used by Koehler by indicating that the crystal shapes which play a part in Koehler's argument, were due to crystallisation on drying the gelatine, and did not exist in the wet gelatine. Schleussner found that adding citric acid increases the distance between the red bands, but had no influence on the white fine lines; additions of citric acid and sodium chloride, both together, and also separately, led him to the conclusion that the sodium chloride substructure was essential to ring formation. He used a washed gelatine, which however still contained halogens, "ausserst stark festgehalten". The method used in the present work, the removing all impurity, followed by the addition of known amounts, would seem to be simpler and more convincing.

¹ R. E. Liesegang, "Ueber die Schichtungen bei Diffusionen" (1907); quoted from Koehler (see below); book not available.

² Fritz Koehler: *Kolloid-Z.*, 19, 65 (1916).

³ C. A. Schleussner: *Kolloid-Z.*, 31, 347 (1922).

Miss Foster¹ investigated the effect of tap water and dilute bleaching powder solution on the Liesegang ring formation, more particularly on the substructure within the red rings. With pure water, the red rings showed no substructure, which may have been because the densest ones were studied (compare Fig. 4); several other observations are recorded which do not bear a clear relation to the present work.

Discussion: The formation of the zone pattern for the silver dichromate in washed gelatine, and for the chloride impurity in unwashed gelatine indicates that in both cases, the inner salt travels to the wall along straight lines; this was also the case with copper ferrocyanide.² To explain why the red bands must have the substructure of the fine lines due to silver chloride is not so easy. If the silver dichromate could be said to be a crystal, it would be easier, but although we have used the word deposit for silver dichromate, and although we feel certain that in some cases at least, a solid is formed, the terms "solid" and "dissolved" applied to gel structures are too loose to have scientific meaning. We intend to add to our information in this respect first, for only on a fullness of facts can a satisfactory theory be rested. It has been noted that the distance between the red rings is increased markedly when the tube is removed from the ice chest even for a short time; on the other hand, the net result for one cake kept at ice chest temperature is about the same as for another kept at room temperature, as Table I will indicate:

TABLE I

¹ Miss A. C. Foster: J. Phys. Chem., 23, 645 (1920).

² Riegel and Widgoff: J. Phys. Chem., 29, 872 (1925).

The age of the gelatine solution (up to 24 or 48 hours) has an effect on the gelatine in the experience of Schleussner¹, and in general our experience confirms this, but more exact information is needed.

Fine lines which, in a photograph at least, look just like the fine substructure due to the impurity, have been obtained by mere moistening followed by drying of a gelatine film.²

Summary: Silver dichromate in washed gelatine forms no line, but an unbroken deposit exhibiting the zone pattern similar to the one formed by copper ferrocyanide; the silver dichromate pattern is free from lines.

Addition of 0.1% NaCl (and smaller amounts) to the solution of washed gelatine causes a reappearance of the red bands; so that it may be said that the red bands do not form unless the substructure due to the chloride impurity is provided.

The chloride impurity itself forms a zone pattern with silver solution.

The penetration of the silver is less in a gelatine gel containing much NaCl, than in another containing only a trace.

THE FREE ENERGY CHANGE IN ADSORPTION AT A SOLID-VAPOUR INTERFACE

BY SAM LENHER AND IVAN ROY McHAFFIE

The change of free energy accompanying the adsorption of molecules of a vapour on a solid surface is an important thermodynamic function. The usefulness of this function would be greatly extended if some relation could be shown to exist between the free energy change and the number of molecules adsorbed per unit area of surface. What follows is an attempt to show this relationship in certain cases which have been recently studied by the authors.¹

FIG. 1

The experimental method was such that the equilibrium vapour pressure of the adsorbed film at the temperature T was measured. Taking as a standard state that of pure vapour in equilibrium with liquid at the temperature T the change of free energy accompanying the adsorption of the vapour was calculated by means of the equation,

$$-\Delta F = RT \log p/p_1 \quad (1)$$

where p is the vapour pressure of the liquid at the standard state, and p_1 is the equilibrium pressure of the adsorbed film.

¹ McHaffie and Lenher: *J. Chem. Soc.*, **127**, 1559 (1925); Lenher: **1926**, 1785; Lenher: Communication to the Chem. Soc., in press.

The amount of vapour adsorbed, expressed here in molecular layers θ , at the temperature T was calculated from the experimental data.

Using water and benzene numerous measurements of the adsorption of the vapours on solid surfaces of glass, silica, and platinum were carried out. Thus it was possible to determine at the temperature T the corresponding values of θ and $-\Delta F$. Since $-\Delta F$ refers to one gram molecule of the substance adsorbed at constant temperature, $-\Delta F$ must be a function of θ . An examination of the data showed that as θ increased $-\Delta F$ decreased and that the relationship was not a linear one. Two general expressions which might give this relation of θ and $-\Delta F$ are,

FIG 2

$$-\Delta F = k_1 e^{-a\theta} \quad (2)$$

$$-\Delta F = k_2 / \theta^n \quad (3)$$

It is evident that if equation (2) expresses this relationship the curve obtained by plotting $\log (-\Delta F)$ against θ would be a straight line. In Fig. 1 $\log (-\Delta F)$ and θ are plotted from the experimental data for water adsorbed on a glass surface and for benzene adsorbed on platinum at the temperatures indicated. Fig. 2 deals with similar data for water on silica and platinum.

The curves obtained for water on glass, benzene on platinum, water on silica, and water on platinum are straight lines. These curves represent the mean of the temperatures plotted, the variations of $\log (-\Delta F)$ with temperature being very small over the range investigated. Only in the case of water on platinum were the isotherms at different temperatures clearly defined. The variation from the straight line is due, generally, to experimental error, but the range of validity of an equation of this type is limited. The lowest

values of θ for which such an equation appears to hold are from 2 to 5 molecular layers. At high values of θ , near saturation, where $-\Delta F$ approaches zero this equation does not hold. This follows since at a finite value of θ , $-\Delta F$ approaches zero and $\log(-F\Delta)$ approaches negative infinity. For values of θ between these limits it has been found that $-\Delta F$ may be expressed as a function of θ by an equation of the form $-\Delta F = ke^{-n\theta}$.

FIG. 3

The equations obtained from the curves of Figs. 1 and 2 are,

water on glass,	$-\Delta F_{300} = 93.4 e^{-0.0249 \theta}$
benzene on platinum	$-\Delta F_{298} = 40.7 e^{-0.030 \theta}$
water on silica,	$-\Delta F_{297} = 66. e^{-0.131 \theta}$
water on platinum,	$-\Delta F_{298} = 87. e^{-0.123 \theta}$
" "	$-\Delta F_{301} = 120. e^{-0.123 \theta}$

To test the applicability of an equation of the type (3) $\log(-\Delta F)$ was plotted against $\log \theta$, since if this equation expresses the relation existing between $-\Delta F$ and θ the curve obtained should be a straight line. These curves for water on glass and water on silica are shown in Fig. 3. The curve obtained for water on glass is a straight line. The relation existing is independent of the temperature at temperatures below 307°K ; above this temperature the values of $\log(-\Delta F)$ are all above the curve drawn.

The data for water on silica at 297°K and 300°K conform to the relation given by (3). The results for the adsorption of water on platinum and benzene on platinum were treated in a similar way but the deviation of the points plotted from the straight line function was much greater than that of the results shown in Fig. 3. The equations obtained for these curves are,

water on silica,	$-\Delta F = 162 \theta^{-1.07}$
water on glass,	$-\Delta F = 1150 \theta^{-0.948}$
water on platinum,	$-\Delta F = 275 \theta^{-1.04}$
benzene on platinum	$-\Delta F = 214 \theta^{-0.89}$

It is interesting to note that the exponent of θ in the four cases is nearly -1 . The empirical equations presented express within stated limits the change of free energy with varying thickness of film adsorbed at a solid-vapour interface.

The authors wish to express to Professor F. G. Donnan, F. R. S. their appreciation of his advice and assistance.

Summary

A relation has been observed between the change of free energy and the amount of a vapour adsorbed per unit area of solid-vapour interface.

Two equations have been tested which give this relationship in certain cases.

Equations expressing $-\Delta F$ as a function of the number of molecular layers adsorbed are given for water on glass, silica, and platinum and for benzene on platinum.

THE REFRACTIVITY OF CARBON MONOXIDE

BY R. A. MORTON AND R. W. RIDING

It has long been known that the interaction between carbon monoxide and oxygen is greatly influenced by the presence or absence of water vapour. Reaction may occur photochemically or it may occur thermally by combustion or explosion.

Dixon¹ investigated the influence of water vapour when combination was effected by sparking between short platinum wires. He found that moist carbon monoxide-oxygen mixtures could be ignited over a very wide range of pressures. Elimination of water vapour brought about a progressive rise in ignition pressure indicating that, in the complete absence of moisture, ignition should not occur even under a continuous rain of sparks. Minute quantities of substances which yield water when sparked with oxygen (hydrogen sulphide, hydrogen chloride, ether, or hexane) acted in exactly the same manner as water in rendering the gaseous mixtures explosive. Compounds not containing hydrogen (including sulphur dioxide) appeared to have no influence on the reaction. The velocity of propagation of the explosion wave was observed to decrease with decreasing moisture content. Dixon regarded the water as a definitely chemical catalyst and suggested formic acid as the intermediate compound, since by passing sparks through moist carbon monoxide the acid is synthesised. Traube, however, draws attention to the formation of hydrogen peroxide.

The combustion of moist carbon monoxide and that of hydrogen have been studied by von Wartenberg and Sieg². These authors established the occurrence of free hydrogen in the former reaction by its diffusion through platinum and they confirmed the presence of hydrogen peroxide in the latter reaction. Accordingly they advanced a step mechanism for the interaction between moist carbon monoxide and oxygen.

Wieland has confirmed Dixon's recognition of the occurrence of formic acid, a result which gains further support from the work of Armstrong and Hilditch,³ in which traces of the acid were obtained by the interaction of carbon monoxide and water at 350° in the presence of lime or ammonia. The equilibrium

has been studied at 156.1° and 217.9° by Branch,⁴ using hydrogen chloride as a catalyst.

Photochemical Reaction

Thiele¹ showed that carbon dioxide is decomposed by light into carbon monoxide and oxygen, a result confirmed by Berthelot and Gaudechon² and by Chadwick, Chapman and Ramsbottom.³

Coehn and Sieper⁴ found that ultra-violet light of wave-length less than $254\ \mu$ brought about the reverse reaction. The degree of dissociation of carbon dioxide varied with the moisture content, the decomposition occurring only to 0.2% when the system was saturated with respect to water vapour at ordinary temperatures, and to about 18% when the gas was dried by means of phosphorus pentoxide. The rate of combination of carbon monoxide and oxygen was uninfluenced by the moisture content. Sulphur dioxide inhibited the decomposition of carbon dioxide by the agency of light. Coehn and Tramm⁵ continued the work and found that moist carbon monoxide-oxygen mixtures could be ignited at almost any pressure by sparking. (Wartenberg and Sieg recorded a critical vapour pressure of 5 mm for water). Gaseous mixtures deprived of moisture by cooling with solid carbon dioxide and ether failed to explode but burned quietly if the cooling had not been prolonged. More thorough drying by the same means reduced the indications of combination to a faint bluish glow round the electrodes. A minute pressure change also occurred. Similar effects occurred in the photochemical reaction. Tramm⁶ considers that the results point rather to a physical, than a purely chemical, role for the water vapour. He points out that on the basis of the Nernst Heat Theorem the concentration of formic acid in the moist carbon monoxide burning at 1000°C should not exceed 1 part in 20,000,000. The mechanism by which water catalyses the photochemical reaction may be concerned with its dipolar electrical nature—an opening of molecular fields of force on the lines of a Stark effect.

The reactivity of moist carbon monoxide must *either* receive an explanation of a special kind, peculiar to the substances reacting (i. e. the step mechanism) *or* it falls into line with the already long list of reactions profoundly affected by moisture.

There is no need to stress the fact that water occupies a unique position as an agency for chemical activation. It matters little whether the energy be supplied by thermal radiation or visible and ultra-violet radiation, the water acts in some way as the acceptor and distributor of energy which would in its absence be ineffective.

It therefore seems pertinent to enquire whether concomitant with the change in chemical reactivity a change in physical properties occurs. The observation of definite change in a property capable of accurate measurement might be expected to throw light on the mechanism of activation.

⁵ Ber., 54B, 1148 (1921).

⁶ Z. physik. Chem., 105, 356 (1923).

Such a property exists in the refractivity. Taylor¹ investigated the influence of side illumination on the refractivity of chlorine. In spite of special precautions to ensure the detection of very small effects the refractivity of illuminated chlorine appeared to be identical with that characterising the gas in its normal state.

In the present investigation on the influence of drying on the refractivity of carbon monoxide a Jamin refractometer made by Hilger was used in conjunction with a monochromator and a cadmium spark. An auxiliary source of white light was used so that the fringes due to the monochromatic light could be seen side by side with those due to the white light. The tube length was determined experimentally by counting the fringes passing across the field of view as dry air slowly entered the evacuated tube. If the refractive index for dry air at a wave-length λ is known the tube length is given by

$$P = N_{\text{NTP}} \lambda / (\mu - 1)$$

μ = refractive index. P = length. N_{NTP} = number of fringes. The standard data of Meggers and Peters² were used. These authors showed that variations in the carbon dioxide content of the air were negligible. In our experiments the line 5085.83 \AA was used throughout. At 760 mm , 15°C , the refractivity for this line, 2779.256×10^7 , permits the length of our tube to be determined as 49.997 cms . Before proceeding to work on carbon monoxide the refractivity of oxygen was measured. Our value of 2717.28×10^7 differs from that calculated from Cuthbertson's data:³— 2727.19×10^7 . An explanation of the discrepancy was found in the different values for air.

Meggers and Peters $(\mu - 1) \times 10^7$	2931.96 at N.T.P.
Cuthbertson	2944.95.

Reducing Cuthbertson's value for oxygen we obtain 2715.9×10^7 as against our result of 2717.28×10^7 , a difference of 5 in 10,000. In our determinations the maximum variation from the mean is 4 in 10,000. Carbon monoxide was now prepared by the interaction of formic and sulphuric acids, it was then passed over soda lime and through concentrated sulphuric acid. The entire apparatus was of glass, no rubber connections being used. The gas was passed through phosphorus pentoxide before use.

The mean of eight determinations of refractivity on the gas dried in this fashion was

$$(\mu - 1) \times 10^7 = 3366.60,$$

whilst the mean of two determinations on the gas further purified by liquefaction (fresh boiling liquid air) was

$$3366.35.$$

The refractivity of carbon monoxide containing 1 mm pressure of water vapour was next determined. The gas was passed through a special saturator

¹ Trans. Faraday Soc., **21**, 614 (1926).

² Bull. Bur. Standards (1918).

³ Proc. Roy. Soc., **83A**, 160 (1910).

containing a sulphuric acid-water mixture.¹ Using the data of Cuthbertson for the refractive index of water vapour ($\mu - 1 \cdot 10^7 = 2538.0$ at 5085 \AA) and assuming the simple mixture law, the refractivity of carbon monoxide at N. T. P. was obtained. Similar data were obtained when the carbon monoxide was saturated with water at room temperatures (16° - 18°).

The results were as follows:—

No. of determinations		$(\mu - 1) \times 10^7$ for 5085.83 \AA	
a		3373.2	Cuthbertson
b		3363.33	Cuthbertson reduced to Meggers and Peters air value.
c	8	3366.60	Gas without liquefaction.
d	2	3366.35	After liquefaction.
e	1	3367.25	1 mm of water vapour
f		3366.24	with 14 mm "

The difference between *a* and *b* is due to the different value for air used in determining tube length.

The following values for the refractivity of carbon monoxide have also been obtained.

Observer	$(\mu - 1) \times 10^7$ at 5461 \AA
Mascart (1874)	3356
Perreau (1896)	3365
Koch (1909)	3361
Gruschke (1910)	3361
Cuthbertson (1920)	3364

Our results are in accord with those of Cuthbertson if the tube length is determined from his data. The values of Meggers and Peters are preferred because of their agreement with the data of Howell² and Dickey.³

Since the refractivity is connected on the classical theory with a dispersive band in the Lyman region which has been identified with valency electrons (Drude) and ionisation potentials⁴ it would seem as if the present results afford a basis for tentative conclusions on the mechanism of chemical activation.

Taylor's failure to observe any change in the refractivity of chlorine activated by illumination coupled with our failure to observe any change with carbon monoxide activated by water vapour point to the absence of any connexion between activation and valency electrons. It seems inevitable that we should regard activation as a process preceding ionisation or dissociation. Evidence for the real existence of such a predissociational state has been obtained by Henri and Teves⁵ in an investigation of the absorption spectrum of sulphur vapour.

¹ Sorel: *Z. angew. Chem.*, **1889**, 272.

² *Phys. Rev.*, (2) **6**, 81 (1915).

³ *Astrophys. J.*, **45**, 188 (1917).

⁴ Morton and Riding: *Phil. Mag.*, (7) **1**, 726 (1926).

⁵ *Nature*, **114**, 894 (1924).

It may be added that it was hoped to investigate the influence of even more intensive drying on the refractivity. As is well known the end plates used in interference work must be optically true and free from distortion. For intensive drying the end plates must be fused on to the tube and not maintained in position by sealing wax. It has so far proved impossible to obtain tubes free from distortional effects.

Summary

The effect of drying on the reactivity of carbon monoxide has been reviewed. The refractivity of oxygen for 5085.83 \AA has been found to be 2717.28×10^7 by means of a Jamin refractometer. This value is lower than that of Cuthbertson, but the discrepancy has been traced to a difference in the refractivity of air as determined by this author and Meggers and Peters, whose value we employed as the standard for fixing the length of tube.

The refractivity of carbon monoxide for 5085.83 \AA was found to be 3366.6×10^7 . Mixtures of carbon monoxide and water vapour obey the simple mixture law, indicating that there is no change in the refractivity concomitant with the change in reactivity which is known to occur in the range of concentrations employed. It is suggested that activation is not concerned with valency electrons.

We express our thanks to Professor E. C. C. Baly, F. R. S. for much interest and advice and to the United Alkali Company for the generous terms of appointment which enabled one of us (R. W. R.) to participate in the work.

SOLUBILITY OF COPPER SULPHATE, MALACHITE AND BURGUNDY PRECIPITATE IN AMMONIUM HYDROXIDE, CARBONATE AND BICARBONATE

BY E. B. HOLLAND AND G. M. GILLIGAN

Introduction

In connection with a rather extended investigation of copper fungicides it was found necessary to determine the solubility of various copper compounds in ammonium hydroxide, carbonate and bicarbonate, and the results so obtained are offered as a contribution to the literature on cuprammoniums.

As Penny (17, p. 5)¹ had shown 3.20 per cent ammonia (NH_3) the most efficient for malachite, approximately that concentration of ammonia was employed in all three solvents. The strength of the solvents was determined by adding a given quantity to an excess of normal acid, and titrating back with normal alkali, using methyl orange as indicator. Precautions were taken to prevent loss of ammonia from the standardized solutions, but occasional fortifying was found necessary. A temperature of 25°C. was adopted, but could not be maintained consistently in the laboratory. In all cases the copper salt was added to a measured quantity of approximately a 3.25 percent ammonia solvent in a 150 c.c. Erlenmeyer flask, stoppered, allowed to stand with occasional shaking to facilitate solution, diluted with water to 100 c.c., and final readings taken after several hours.

Solutions near saturation will often reprecipitate on standing, due to loss of ammonia from the liquid phase to the gaseous, therefore, the amount of solvent reported should exceed *slightly* that actually required for solution.

For convenience the various determinations will be classified, first, according to the solvent, into (1) ammonium hydroxide, (2) ammonium carbonate, (3) ammonium bicarbonate, and secondly, according to the source of copper into, (a) copper sulphate, (b) malachite, (c) Burgundy precipitate.

1. Ammonium Hydroxide

(a) Copper Sulphate

The amount of ammonium hydroxide (NH_4OH) and of ammonia (NH_3) required to give clear solutions with 1.0 gram and 0.1 gram of powdered, selected crystals of C. P. copper sulphate (Cu 25.37 per cent, equivalent to 99.66 per cent theoretical) dissolved in approximately 3.25 per cent solution of NH_3 , and subsequently diluted to 100 c.c. and the calculated amount for each 100 c.c. of added water between these limits are reported in Table I.

¹ Reference is made by number (*italic*) to "Literature cited".

TABLE I
Ammonium hydroxide and ammonia required to give a clear
solution with copper sulphate

Theoretical ratio		
Gram mols of ammonium hydroxide per mol of copper sulphate		0.14035
Gram mols of ammonia per mol of copper sulphate		0.06821
Gram mols of ammonium hydroxide per (n) ¹ mols copper		0.55133
Gram mols of ammonia per (n) ¹ mols copper		0.26793
Experimental data		
Copper sulphate to a clear solution in 100 c.c.	1.0 Gms.	0.1 Gms.
Mols of ammonium hydroxide	4.5	23.0
Mols of ammonia	4.5	23.0
Grams of ammonium hydroxide	0.63158	0.32281
Grams of ammonia	0.30695	0.15688
C.c. of commercial ammonia water (Sp. gr. 0.90)	1.26	0.65
Calculated		
Grams of ammonium hydroxide per 100 c.c. of water		0.28850
Grams of ammonia per 100 c.c. of water		0.14021
C.c. commercial ammonia water (Sp. gr. 0.90)		0.58

The amount of commercial ammonia water (*Aqua Ammoniae Fortior*) specific gravity 0.90, is calculated on the minimum requirement of the U. S. P. (23, pp. 56, 544) or 27 per cent ammonia (NH₃) by weight, equivalent to 0.2429 grams in 1 c.c. at 25°/25°C.

Millardet and David (16), Lasserre (13) and Butler (2, p. 238) obtained for 1 per cent solution of copper sulphate 1.53, 1.50 and 1.50 c.c. of ammonia water respectively, a quantity larger than was required in this laboratory. Horn (12, p. 476) cites 5.48 mols of ammonia for a 1.25 per cent solution. That a greater proportion of ammonia is required to maintain equilibrium on dilution is generally recognized, Pickering (7, p. 18) obtained 1.6 c.c. and Butler (2, p. 238) 0.7 c.c. of ammonia water for a 0.1 per cent solution of copper sulphate, results appreciably higher than that reported.

There is naturally a difference of opinion as to the reactions involved in the production of cuprammonium sulphate, but the following are intended to embrace substantially the views of Chester (4, p. 68), Dawson and McCrae (5, p. 1258; 6, p. 1666), Horn (12, p. 475) and Prescott and Johnson (22, p. 106).

¹ The number of mols of copper in the compound.

By analogy one may presuppose in reaction (1) $5\text{CuO} \cdot \text{SO}_3$ and $10\text{CuO} \cdot \text{SO}_3$ from 6.4 mols and 7.2 mols of ammonia as in the case of fixed alkalis, shown by Pickering (18, p. 1983; 19, pp. 1991, 1997, 2000; 21, pp. 1852, 1855; 9, pp. 26, 27), but there is no evidence to that effect. In reaction (3) (n) must be 0.5 mols per mol of copper sulphate for a 1 per cent solution, as shown in Table I, but as (n) increases rapidly on dilution, dissociation phenomena must be involved. Furthermore dry commercial cuprammonium sulphate, $\text{Cu}(\text{NH}_3)_4\text{SO}_4 \cdot \text{H}_2\text{O}$, although an unstable product, required only a small amount of additional ammonia to clear a 1 per cent solution which would tend to confirm the value of (n).

Theoretically the precipitate obtained on dilution, reaction (5), should be largely basic sulphate, but in some instances at least considerable hydroxide results which on filtering and drying is readily converted into basic carbonate, as shown by the analysis of the following sample prepared in the laboratory.

	Per cent
Cupric oxide, CuO	69.47
Sulphuric trioxide, SO_3	6.72
Carbon dioxide, CO_2	9.27
Water by difference, H_2O	14.54
	<hr/>
	100.00

Hypothetical combinations

Water, H_2O	2.606
Tribasic copper sulphate, $4\text{CuO} \cdot \text{SO}_3 \cdot 4\text{H}_2\text{O}$	39.483
Basic copper carbonate, $\text{CuCO}_3 \cdot \text{Cu}(\text{OH})_2$	46.594
Copper hydroxide, $\text{Cu}(\text{OH})_2$	11.317
	<hr/>
	100.000

With proper control, however, and less attention to yield a higher proportion of basic sulphate should be recovered.

The solubility of tribasic copper sulphate ($4\text{CuO} \cdot \text{SO}_3 \cdot 4\text{H}_2\text{O}$) in ammonia could not be determined as a sample of satisfactory quality was not obtainable at the time.

(b) *Malachite*

The amount of ammonium hydroxide and of ammonia required to give clear solutions with 0.5 gram and 0.1 gram of Merck's, C. P., green copper carbonate (moisture 1.58 per cent, Cu 54.30 per cent, equivalent to 94.45 per cent pure) dissolved in approximately 3.25 per cent solution of ammonia,

and subsequently diluted to 100 c.c., and the calculated amount for each 100 c.c. of added water between these limits are reported in Table II. As the quantity of 3.25 per cent ammonia necessary for 1 gram of malachite would exceed 100 c.c., 0.5 gram was the maximum amount employed. Technical or commercial malachite is said to contain only 50 to 52 per cent of copper.

TABLE II

Ammonium hydroxide and ammonia required to give a clear solution with malachite

Theoretical ratio

Gram mols of ammonium hydroxide per mol of malachite	0.15848
Gram mols of ammonia per mol of malachite	0.07701
Gram mols of ammonium hydroxide per (n) ¹ mols of copper	0.27566
Gram mols of ammonia per (n) ¹ mols of copper	0.13396

Experimental data

Malachite to a clear solution in 100 c.c.	0.5 Gms.	0.1 Gms.
Mols of ammonium hydroxide	60.0	65.0
Mols of ammonia	60.0	65.0
Grams of ammonium hydroxide	4.75440	1.03012
Grams of ammonia	2.31030	0.50057
C.c. of commercial ammonia water (Sp. gr. 0.90)	9.51	2.06

Calculated

Grams of ammonium hydroxide per 100 c.c. of water	0.09905
Grams of ammonia per 100 c.c. of water	0.04814
C.c. of commercial ammonia water (Sp. gr. 0.90)	0.20

Investigators do not agree as to the reaction involved in the solution of malachite in ammonia. Gastine (11, p. 115) claims the resultant is cuprammonium carbonate; Pickering (8, p. 20) mainly cuprammonium carbonate; Chester (4, p. 68) cuprammonium carbonate and cuprammonium hydroxide, and Butler (2, p. 242) cuprammonium hydroxide. Mellor (15, pp. 151, 152, 275) cites considerable data, but to what extent applicable is uncertain. Evidently cuprammonium carbonate could not be formed in entirety unless sufficient carbon dioxide was absorbed to satisfy the reaction (1), but a mixture of cuprammonium carbonate and of cuprammonium hydroxide (2), or cuprammonium hydroxide alone, (3) offers a more feasible hypothesis.

¹ The number of mols of copper in the compound.

As the amount of ammonia entering combination constitutes but a small proportion of that required for solution, due probably to limited surface area, and the resistance of malachite to dissociation, the mols reported, Table II, are of little significance in designating the reaction. Reaction (3) seems the most probable, however, as the solution dissolves cellulose, does not deposit malachite on standing, according to Butler (2, p. 242), and yields the hydroxide on dilution. A precipitate prepared in the laboratory by dilution, filtration, and drying in vacuo at room temperature, gave a blue resultant which contained 61.98 per cent of copper, and a trace of carbon dioxide equivalent to about 95 per cent cupric hydroxide. The carbon dioxide content must vary with the conditions of precipitation and exposure. The cuprammonium hydroxide formed with a small excess of ammonia is presumably the diammino obtained by Dawson and McCrae (5, p. 1257), and by Bonsdorff (1), but with a large excess of ammonia the tetrammino is more probable as shown by Bonsdorff.

The solubility of azurite ($2\text{CuCO}_3 \cdot \text{Cu}(\text{OH})_2$) in ammonia could not be determined as the only sample available contained 12.12 per cent of ammonia insoluble matter which masked the end point.

(c) *Burgundy Precipitate*

The amount of ammonium hydroxide and of ammonia required to give clear solutions with aliquots of washed Burgundy precipitate, equivalent to 1.0 gram and 0.1 gram of copper sulphate, dissolved in approximately 3.25 per cent solution of ammonia, NH_3 , and subsequently diluted to 100 c.c. and the calculated amount for each 100 c.c. of added water between these limits, are reported in Table III.

The Burgundy mixture (soda Bordeaux, bouillie Bourguignonne) was prepared according to Masson (14, p. 816) as modified by Pickering (10, p. 86; 20, pp. 1412, 1414, 1428).

Particular care was observed in gradually adding a *cool*, dilute solution of copper sulphate to a similar solution of sodium carbonate in order to reduce the loss of carbon dioxide to a minimum, and to favor the formation of a basic carbonate. The reverse procedure is likely to yield more or less basic sulphate. The precipitate was allowed to coalesce, filtered, washed substantially free from sodium sulphate and sodium bicarbonate, transferred to a graduated flask, and made to volume. Upon standing the washed precipitate is gradually converted into malachite. The results are reported in terms of copper sulphate, less small unavoidable errors due to incomplete precipitation of the copper and mechanical losses, but assuming that one gram of copper sulphate yields approximately 0.47570 grams of basic carbonate ($5\text{CuO} \cdot 2\text{CO}_2 \cdot 6\text{H}_2\text{O}$) the results could be readily recalculated to the latter basis.

TABLE III

Ammonium hydroxide and ammonia required to give a clear solution with washed Burgundy precipitate, in terms of copper sulphate

Theoretical ratio

Gram mols of ammonium hydroxide per mol of copper sulphate	0.14035
Gram mols of ammonia per mol of copper sulphate	0.06821

Grams of ammonia per 100 c.c. of water	0.11747
C.c. of commercial ammonia water (Sp. gr. 0.90)	0.48

The reaction for solution is presumably similar to that of malachite.

The solubility of sodium bicarbonate Bordeaux (Bordeaux bouillie celeste), (8, p. 291; 20, p. 1414) precipitate in ammonia was not determined as the precipitation was considered too variable and incomplete to warrant the examination.

The solubility on a one per cent basis of copper sulphate, malachite and washed Burgundy precipitate, and of the copper present, in ammonium hydroxide and its ammonia content, is summarized in Table IV, together with the dilution or hydrolytic equivalent.

TABLE IV

Solubility and hydrolytic equivalent of the copper compounds in ammonium hydroxide

On a one per cent basis	Ammonium hydroxide Grams	Ammonia Grams

Hydrolytic equivalent	0.45323	0.22027

¹ Calculated on a theoretical basis from the copper in the product tested.

Summary of Results with Ammonium Hydroxide

1. The solubility of malachite, washed Burgundy precipitate, and copper sulphate in ammonium hydroxide, increases in the order named or directly with their dispersion. Conversely the amount of ammonium hydroxide required to form soluble cuprammonium decreases in the same order.
2. The solubility of the copper in ammonia is in the same order but more uniform.
3. Ammonium hydroxide soluble cuprammoniums are unstable on dilution. The "hydrolytic equivalent" or the amount of solvent required to counteract dilution, is in the reverse order of the solubilities and, in terms of copper and of ammonia, fairly proportional.
4. Ammonium hydroxide soluble cuprammoniums are unstable in relatively high concentrations of ammonia, and under the influence of heat, decomposing with the formation of dicupric hydroxide or oxide.

2. Ammonium Carbonate

The solubility of the several copper compounds in ammonium carbonate was determined in the same manner as in ammonium hydroxide. Ammonium carbonate (Ammonii Carbonas) consists of varying proportions of ammonium bicarbonate (NH_4HCO_3) and ammonium carbamate ($\text{NH}_4\text{NH}_2\text{CO}_2$), but is generally considered as of equal mols and substantially of equal parts by weight 79.048: 78.064. The amount of commercial ammonium carbonate is calculated on the minimum requirement of the U. S. P. (23, pp. 47, 48)—"to yield 30 per cent of ammonia (NH_3)" by weight, equivalent to 92.245 per cent theoretical. A solution of approximately 3.25 per cent ammonia (NH_3) content was employed and the copper salt added to the solvent, aiming to produce cuprammonium carbonate. Loss of carbon dioxide could not be entirely prevented however.

(a) Copper Sulphate

Mols of ammonia	7.5	9.0
Grams of ammonium carbonate	1.57293	0.18875
Grams of ammonia	0.51158	0.06139
Grams of commercial ammonium carbonate	1.71	0.20

TABLE V (continued)

Calculated

Grams of ammonium carbonate per 100 c.c. of water	0.03495
Grams of ammonia per 100 c.c. of water	0.01137
Grams of commercial ammonium carbonate	0.04

Assuming that cuprammonium carbonate is formed in entirety, the following tentative reaction, complying with the results obtained with a one per cent solution of copper sulphate, Table V, is suggested:

Four mols of ammonium carbonate to 3 of copper sulphate would satisfy the equation, but evidently greater excess is necessary for the reaction under the conditions employed. On evaporation the solution appears to yield malachite.

A one per cent solution of commercial cuprammonium sulphate required about 0.5 mols of ammonium carbonate per mol of sulphate to clear, in which case only a small proportion at best could have been converted into cuprammonium carbonate

(b) *Malachite*

TABLE VI

Ammonium carbonate required to give a clear solution
with malachite

Theoretical ratio

Gram mols of ammonium carbonate per mol of malachite	0.71041
Gram mols of ammonia per mol of malachite	0.07701
Gram mols of ammonium carbonate per (n) mols of copper	1.23574

The following tentative reaction is suggested as complying with the results secured with a one per cent solution, Table VI.

Four mols of ammonium carbonate to 3 mols of malachite would furnish sufficient ammonia to satisfy the equation but not for the reaction. On evaporation the solution apparently yields malachite or other basic carbonate.

(c) Burgundy Precipitate

The washed Burgundy precipitate was prepared as previously described, and the solubility determined on aliquots. The results are reported in terms of copper sulphate, but may be recalculated to basic carbonate ($5\text{CuO} \cdot 2\text{CO}_2 \cdot 6\text{H}_2\text{O}$), assuming that 1 gram of copper sulphate yields approximately 0.47570 grams of basic carbonate.

Copper in washed Burgundy precipitate	8.26687	2.68871
Hydrolytic equivalent	0.00000	0.00000

Summary of Results with Ammonium Carbonate

1. The solubility of washed Burgundy precipitate, malachite and copper sulphate in ammonium carbonate increased in the order named, but is more uniform than in the case of ammonium hydroxide. The lower solubility of Burgundy precipitate ($5\text{CuO} \cdot 2\text{CO}_2 \cdot 6\text{H}_2\text{O}$) as compared with malachite ($\text{CuCO}_3 \cdot \text{Cu}(\text{OH})_2$) may be due in part to the lower ratio of CO_2 : Cu, as the physical character of the former is naturally more promising.

2. The solubility of the copper in terms of ammonia is fairly constant, and in marked contrast to ammonium hydroxide in this respect.

3. Ammonium carbonate soluble cuprammoniums are more stable on dilution than the ammonium hydroxide soluble. Copper sulphate required a small excess of solvent to prevent partial hydrolysis, but malachite and Burgundy precipitate did not require any between the limits tested.

4. Ammonium carbonate soluble cuprammoniums are less likely to decompose with the formation of cupric oxide than ammonium hydroxide soluble.

3. Ammonium Bicarbonate

Ammonium bicarbonate (NH_4HCO_3) was also employed as a solvent in the same way as ammonium carbonate. There is no prescribed standard, but as the compound is relatively more stable than the carbonate, 95 per cent of the theoretical ammonia content was adopted as a reasonable requirement for the commercial product, equivalent to 20.47 per cent of ammonia (NH_3) by weight.

¹ Calculated on a theoretical basis from the copper in the product tested.

Copper in washed Burgundy precipitate	12.47778	2.68871
Hydrolytic equivalent	0.00000	0.00000

Summary of Results with Ammonium Bicarbonate

1. The solubility of washed Burgundy precipitate, malachite and copper sulphate in ammonium bicarbonate increased in the order named, and is even more uniform than with ammonium carbonate. The bicarbonate, however, proved less efficient than the carbonate.

2. The solubility of the copper in terms of ammonia is nearly constant, but in a new order malachite, copper sulphate and Burgundy precipitate.

The same amount of ammonia in bicarbonate and carbonate proved equally effective on the copper in malachite and on the copper in Burgundy precipitate, but the ammonia in the bicarbonate is less effective than in the carbonate, on the copper in copper sulphate.

3. In the case of copper sulphate more bicarbonate was required to prevent hydrolysis than of carbonate, but with malachite and Burgundy precipitate no additional solvent was required between the limits tested.

Summary of Results with the Different Solvents

1. The effectiveness of ammonium bicarbonate, ammonium carbonate and ammonium hydroxide on copper sulphate in producing soluble cuprammoniums increases in the order named, and hold equally true of the ammonia content, but not in the same magnitude.

2. The effectiveness of ammonium hydroxide, ammonium bicarbonate and ammonium carbonate on malachite increases in the order named, but the ammonia in carbonate and bicarbonate is equally effective.

3. The effectiveness of ammonium bicarbonate, ammonium hydroxide and ammonium carbonate on Burgundy precipitate increased in the order named, but the ammonia in carbonate and bicarbonate is equally effective.

¹ Calculated on a theoretical basis from the copper in the product tested.

4. The hydrolytic equivalent of the cuprammoniums decreases in the following order, copper sulphate-ammonium hydroxide, Burgundy precipitate-ammonium hydroxide, copper sulphate-ammonium bicarbonate, malachite-ammonium hydroxide, and copper sulphate-ammonium carbonate. Malachite and Burgundy precipitate with ammonium carbonate and ammonium bicarbonate required no additional solvent between the limits tested. In terms of ammonia malachite-ammonium hydroxide preceded copper sulphate-ammonia bicarbonate, otherwise in the same order as above. In general the hydrolytic equivalent was inversely proportional to the amount required for solution.

MUTAROTATION. I.

Velocity of Mutarotation of α Glucose in Methyl Alcohol and Water

BY FREDERICK PALLISER WORLEY AND JOHN CLARK ANDREWS

The mutarotation of sugars has received a great deal of attention during recent years, and various explanations of the mechanism of the action have been advanced, but none of these explanations has been found entirely satisfactory, nor have they received wide acceptance. Baker, Ingold and Thorpe¹ stimulated interest in the problem by an attempted critical investigation of the explanations of the mechanism of mutarotation advanced by E. F. Armstrong², Lowry³ and Jacobsen and Stelzner⁴. The present investigation was undertaken with a view to criticising conclusions arrived at by Baker, Ingold and Thorpe. Lowry⁵ in the meantime has adversely criticized their work and has pointed out that their mathematical investigation of the problem is unsound. He also advanced the subject by pointing out the similarity between mutarotation and the hydrolysis and saponification of esters.

In spite of the large amount of experimental work already carried out by numerous investigators it would appear that all the facts necessary for the solution of the problem have not been available, and a considerable amount of work has recently been carried out using various sugars and their methylated and other derivations in various solvents.⁶

The experimental basis of the work of Baker, Ingold and Thorpe was the effect of water on the velocity of mutarotation of α glucose in methyl alcohol. The proportion of water did not exceed 2% and no account was taken, as was pointed out by Lowry, of minute amounts of catalysts present. It appeared desirable to ascertain the velocity in mixtures of highly purified methyl alcohol and water in all proportions. This has been done in the present investigation but although special care was taken in the purification of materials used it is not likely that all traces of catalytic substances have been removed. Even were it possible to obtain the substances absolutely pure, unavoidable contact with the atmosphere introduces impurities likely to have some catalytic action.

Purification of Materials

α Glucose was three times recrystallised from specially purified ethyl alcohol, final traces of alcohol being removed by careful warming under reduced pressure. The product was stored in a flask connected to a second flask containing phosphorus pentoxide.

Methyl alcohol A. R. obtained from British Drug Houses, was found to contain traces of acetone. The acetone was converted into iodoform by means of iodine and caustic potash. After filtering, the liquid was refluxed for eight hours over freshly burnt lime. It was then distilled through a Young's Evaporator column of eight sections and the middle portion collected in a waxed vessel after condensation in a condenser having an inner tube of silica. The boiling point was constant $64.56\text{--}64.57^{\circ}\text{C}$ $D_{40}^{25} = 0.78646$. Water was purified in the usual way and was kept only for short periods and always in waxed vessels.

Apparatus. The polarimetric apparatus, thermostat, and temperature control were similar to those previously described by one of us¹ and the source of illumination was a Cooper Hewitt mercury arc lamp. In order to minimise surface action, the polarimeter tubes were waxed before each experiment with purified paraffin wax dissolved in petroleum ether. In carrying out the determination of the velocity of mutarotation there was generally a considerable unavoidable interval after adding the sugar to the solvent before a reading could be taken. This was chiefly due to the time required for the solution of the glucose in mixtures rich in methyl alcohol. The determinations were all carried out at 25°C .

Experimental Results

The velocity of mutarotation of glucose in methyl alcohol alone varied considerably in different determinations although the procedure was apparently the same. No explanation for this variation has yet been found, but it is apparently due to varying contamination by traces of impurity. The velocity constant obtained was in all cases considerably lower than values recorded by other investigators. In several cases, there was a distinct lag at the beginning, during which the velocity of mutarotation was almost or entirely arrested, similar to the lag recently observed by Lowry and Richards². In one experiment, the velocity constant was exceptionally low, due possibly to a prolongation of the period of lag observed in other experiments. Subsequent attempts have failed to reproduce this low value. The details of this experiment are given in Table I.

A slight temporary rise of temperature occurred shortly after the experiment had proceeded thirteen hours. Observations were continued for another ten hours and the mean velocity constant for the latter part of the experiment was found to be the same as above, viz. 0.000030 .

In other experiments the values obtained were 0.0333 , 0.0344 , 0.0339 , 0.0387 , 0.0345 , 0.0331 .

The lowest values previously recorded are those of Lowry and Richards at 20° viz. 0.0008 and 0.0006 . Baker, Ingold and Thorpe, working at 44.8° , found $K = 0.00275$ calculated on the same basis. Taking into account the difference in temperature our lowest value is about twenty-five times smaller than previous values, suggesting the possibility of still lower or even zero values being arrived at under ideal conditions.

The velocity of mutarotation of α glucose in water has been measured by Osaka¹, Hudson², Kuhn and Jacob³ and others. Kuhn and Jacob obtained a velocity of 0.0104 and Osaka and Hudson each obtained 0.0096. In three determinations we obtained the following values 0.00957, 0.00956, 0.00950 closely agreeing with the value obtained by Osaka and Hudson.

The velocity of mutarotation in mixtures of methyl alcohol and water in proportions varying from 0 to 100 per cent water are given in Table II, the proportions being expressed as molecular percentages. The results are shown

FIG. 1

graphically in the accompanying curve (Fig. 1) in which the velocity constants are plotted as ordinates and the molecular percentages of water and methyl alcohol as abscissae.

It should be remarked that the low values of K at a concentration of 89 per cent methyl alcohol were obtained at about the same time as the lowest value of K for methyl alcohol alone, viz. 0.043. Since the lowest values at any concentration are probably obtained when the experimental conditions are most satisfactory extra weight should be given to low values. In the figure the full curve is drawn giving equal weight to all values while the dotted curve is drawn through points representing the minimum values obtained. From the curve it is seen that within the limits of experimental error the velocity constants lie on a smooth curve, and also that the effect of the addition of methyl alcohol to water has a much greater effect in decreasing the velocity than the addition of water to methyl alcohol has in increasing the velocity of mutarotation.

The comparatively small effect of the addition of small amounts of water to methyl alcohol is in accordance with the results of determinations made by Baker, Ingold and Thorpe. We do not, however, interpret the experimental results in the same way, but are leaving the discussion of the mechanism of the process till a later communication after more experimental data have been obtained.

Summary

1. The velocity of mutarotation of α glucose in methyl alcohol, water and mixtures of methyl alcohol and water has been determined at 25°C.
2. The value of the velocity constant obtained in the case of water was approximately the same as the lowest value previously recorded
3. In the case of methyl alcohol a much lower value was obtained than any recorded by previous investigators.
4. The velocity constants obtained in mixtures of methyl alcohol and water lie on a smooth curve.

5. Addition of small amounts of methyl alcohol to water has a much greater effect in reducing the rate of mutarotation than the addition of water to methyl alcohol has in increasing the rate.

We have to acknowledge our indebtedness to the Royal Society for a grant to one of us (F. P. W.) towards the cost of polarimetric apparatus, and to the Duffus Lubecki Scholarship Fund for a Scholarship which enabled one of us (J. C. A.) to take part in this investigation.

THE ABSOLUTE ZERO OF THE EXTERNALLY CONTROLLABLE ENTROPY AND INTERNAL ENERGY OF A SUBSTANCE OR MIXTURE

BY R. D. KLEEMAN

The properties of the internal energy and entropy of a substance at the absolute zero of temperature and the connection of these properties with those at higher temperatures has recently attracted a considerable amount of attention, and given rise to a good deal of experimental research. The importance of the subject was probably first recognized by Nernst who enunciated his well known heat theorem in this connection. The development of the subject ultimately resulted in a theorem which is often called the third law of thermodynamics. The object of this paper is to show that these results are only cases of a much more general result, which can be deduced directly from results of an axiomatic character.

1. *The Division of the Internal Energy and Entropy into Two Parts.*

The internal energy of a substance or mixture of given mass may be divided into two parts, one of which is a function of the variables temperature and volume only, while the remaining part is independent of these quantities. The first part will accordingly be externally controllable while this will not be the case with the other part, and hence these two parts will be called the externally controllable and externally uncontrollable internal energy of the system. The heat absorbed when the temperature of a substance is increased, or its volume is isothermally increased, are examples of changes in the controllable internal energy of a system. Changes in the uncontrollable internal energy would evidently be spontaneous. An example of such a change is the ejection of α and β rays during radio-active changes, for these changes are independent of temperature and volume, and therefore take place spontaneously. The liberated energy in such a case, however, becomes controllable internal energy. It would be interesting to know if the reverse may happen.

Similarly the entropy of a substance or mixture may be divided into two parts, one of which is externally controllable while the other is not.

In speaking of the thermodynamical equilibrium of a system, such as a mixture in a number of phases, it is tacitly assumed that the nature of the equilibrium will not change unless made to do so from the outside by a change in temperature, volume, or masses of some of the constituents. The equilibrium therefore depends upon the controllable internal energy and entropy of the system. Similarly, any reversible process in thermodynamics is externally controllable, and therefore involves changes only in the controllable internal energy and entropy. These particular quantities are therefore of great thermodynamical importance.

If u denote the controllable internal energy of a mass of matter we may accordingly write

$$u = \psi_u(T, v, M_a, M_b, \dots) \quad (1)$$

where v denotes the volume of the matter at the absolute temperature T , and M_a, M_b, \dots denote the masses in gram atoms of the constituent a, b, \dots . Similarly if S denotes the controllable entropy we may write

$$S = \psi_s(T, v, M_a, M_b, \dots) \quad (2)$$

Since u by definition is the controllable internal energy it will have a zero value for certain values of v and T . For if this were not so let u_1 denote the least possible value u can have. Now the internal energy u_1 could not be externally controlled, or its value reduced by changes in the values of v and T , and therefore it does not consist of controllable internal energy. The values of v and T corresponding to a minimum of u would therefore give a zero value to the controllable internal energy.

Similarly it can be shown that the controllable entropy is zero corresponding to its minimum value for certain values of v and T .

If a surface is plotted with v, T , and u as axes, u being taken in its general sense, it will be evident that the zero of the controllable internal energy corresponds to a point where a plane parallel to the v and T axes touches the surface. Similarly in the case of a surface with v, T , and S as axes, the zero of controllable entropy corresponds to the point where a plane parallel to the v and T axes touches the surface. The zero of the controllable internal energy and entropy may definitely be determined, the reasoning depending in the main on the following theorem:—

2. *The Specific Heat $\left(\frac{\partial u}{\partial T}\right)_v$ at Constant Volume of a Substance or Mixture can have only Positive Values.*

This theorem is a direct consequence of our fundamental conceptions of heat and temperature, according to which an increase of temperature of a mass of matter kept at constant volume is associated with an increase in the heat content. It can therefore be shown to be intimately connected with the laws of thermodynamics. As is well known the thermodynamical scale of temperature is founded on Carnot's cycle. This depends on heat flowing to a substance or mixture on expanding it isothermally and on its temperature decreasing on expanding it adiabatically. It may be remarked that it is one of our fundamental experiences with matter that its temperature may be decreased to any desired extent by adiabatically decreasing its volume sufficiently. Under these conditions only can the heat taken in at the higher temperature during the cycle be larger than the heat given out at the lower temperature, the difference representing the external work done, as is demanded by the laws of thermodynamics. It follows also from these laws that the amount of work obtained is independent of the nature of the substance or mixture used, provided we work between the same temperature limits and the same amount of heat disappears as such, on which considerations the absolute temperature scale is based.

Now suppose that a mass of matter has its temperature increased from T_1 to T_2 at constant volume, giving rise to an algebraical increase in entropy equal to $\sum_{T_1}^{T_2} \frac{C_v}{T} \cdot \partial T$, where C_v denotes the specific heat at constant volume. Next suppose that the volume is adiabatically increased till the temperature has fallen to T_1 . Lastly suppose that the volume of the matter is isothermally decreased till it regains its initial value, during which a quantity of heat Q is given out, and a corresponding decrease Q/T_1 in entropy takes place. This decrease is equal to the foregoing increase, and hence

$$\sum_{T_1}^{T_2} \frac{C_v}{T} \cdot \partial T = \frac{Q}{T_1}$$

According to this equation C_v or $\left(\frac{\partial u}{\partial T}\right)_v$ is positive.

It may also be noted that since the theorem is based on the laws of thermodynamics, which are the outcome of experience, physically absurd results (in the light of our experience) would be obtained if we suppose that the theorem does not hold. Thus it is evident that if the temperature of the surrounding medium is increased by ∂T an initial flow of heat to the substance will take place, whether its specific heat is positive or negative, otherwise nothing would ultimately happen with the substance. This will be attended by an absorption of heat. It will then be found that if we suppose that the specific heat is negative it may have an indeterminate value, or the lowering or raising of the temperature of the substance over a finite range can only be carried out by periodically reversing the flow of heat. These are of course absurd results in the light of our experience. *

Besides the above theorem some other results will be necessary in order to determine the zero of the controllable internal energy and entropy whose truth according to our experience is even more obvious, and which will therefore be designated as postulates.

3. *The Coefficients $\left(\frac{\partial p}{\partial T}\right)_v$, $\left(\frac{\partial p^2}{\partial T^2}\right)_v$ cannot have Infinite Values.*

Since the pressure of a substance is due to the motion of translation of the molecules, an increase in the magnitude of this motion through an increase of temperature is not likely to be attended by an infinite increase in pressure, or $\left(\frac{\partial p}{\partial T}\right)_v$ cannot have an infinite value. For the same reason $\left(\frac{\partial^2 p}{\partial T^2}\right)_v$ cannot have an infinite value.

We shall now proceed to apply the results of this and the preceding Section.

4. *The Absolute Zero of the Controllable Internal Energy of a Mass of Matter.*

Let us consider a mass of matter in the condensed state under the pressure of its vapour at the absolute zero of temperature. It can be shown that the controllable internal energy always increases in passing from this state

to another physical possible state. Since such a change is brought about by a variation of v and T , it may be noted at the outset that the controllable internal energy only will undergo a change. Thus suppose that the matter is isothermally compressed. This can be shown to be attended by an increase in internal energy.

On multiplying the thermodynamical equation

$$\left(\frac{\partial u}{\partial v}\right)_T = T \left(\frac{\partial p}{\partial T}\right)_v - p \quad (3)$$

by ∂v and integrating it between the limits v and v' , u and u' we obtain

$$u - u' = \int_{v'}^v \left\{ T \left(\frac{\partial p}{\partial T}\right)_v - p \right\} \cdot \partial v$$

At the absolute zero of temperature this equation becomes

$$u - u' = - \int_{v'}^v p \cdot \partial v \quad (4)$$

since $T = 0$, and $\left(\frac{\partial p}{\partial T}\right)_v$ is not infinite according to the postulates in the

preceding Section. If v is taken equal to v_0 , the volume of the mixture in the condensed state at the absolute zero of temperature under the pressure of its vapour, and v' is less than v_0 , p is positive for values of v lying between v_0 and v' inclusive. Hence $u' - u$ is positive, or if the volume is isothermally decreased from v_0 to v' this is attended by an increase in u .

This result follows also from the fact that the atoms of a substance in the condensed state at the absolute zero of temperature are in equilibrium under their forces of attraction and repulsion. Hence when the volume is decreased repulsion is the outstanding force, and the internal energy is accordingly increased during a process of compression.

If the volume of the substance is plotted against its temperature the foregoing operation corresponds to passing from the point v_0 to the point v' in Fig. 1.

Next suppose that the substance kept at the constant volume v' has its temperature increased to T , which in Fig. 1 corresponds to passing from the point v' to the point T . This is attended by an increase in internal energy according to the theorem in Section 2. Thus the whole process, since it involves variations of v and T , gives rise to an increase in the controllable internal energy. This result will evidently apply to any point lying in the compartment in Fig. 1 made by the line $v_0 a$ and the positive axes of v and T .

Next suppose that the mass of matter in the same initial state as before, namely in the condensed state in contact with its vapour at the absolute zero of temperature, has its volume isothermally increased to v'' , which corresponds to passing from the point v_0 to the point v'' in Fig. 1. The matter

would divide itself into a solid and vaporous phase. The amount of matter in the latter phase would however be zero, since the pressure is zero. The process is therefore not attended by a change in internal energy.

Since, when v'' is infinite the amount of evaporated matter may be finite, we may proceed more strictly thus: The heat absorbed, if any is absorbed, can only have a positive value according to the fundamental properties of Carnot's cycle pointed out in Section 2. Now the external work done is equal to ART , where A is a constant, and therefore zero, since $T = 0$. Therefore a positive increase in internal energy only can take place.

FIG. 1

FIG. 2

Next suppose that the temperature of the matter is raised to T keeping the volume v'' constant, which corresponds to passing from the point v'' to the point T in Fig. 1. This is attended by an increase in internal energy according to the theorem in Section 2. Thus the controllable internal energy of the matter has been increased during the process. This result will evidently also apply to any point in the space in Fig. 1 to the right of the line $v_0 a$.

It follows then that the total internal energy of the mass of matter in its initial state has a smaller value than for any other physically possible state. Therefore according to the definition of and properties of the controllable internal energy given in Section 1, its value is zero, when the matter is in the condensed state under the pressure of its vapour at the absolute zero of temperature.

We may now proceed to the consideration of the entropy.

5. *The Absolute Zero of the Controllable Entropy of a Mass of Matter*

The absolute zero of the controllable entropy according to Section 1 corresponds to the state for which it can be shown that the controllable entropy has a smaller positive value than for all other physically possible states. Such a state should exist. For suppose that the entropy is measured from a given state chosen arbitrarily. Let the state of greatest negative entropy be obtained corresponding to this state. We may then transfer the zero to the latter state and measure the entropy from this state. It would evidently correspond to the foregoing definition of the zero of controllable entropy.

Let the point u_0 on the v axis in Fig. 2 correspond to the zero of the controllable internal energy. Let the curve ab be an adiabat corresponding to zero entropy. Now as we pass from the zero point of internal energy u_0 to the point a on the adiabat which corresponds to the same volume, the internal energy is increased, and hence the entropy is increased. Therefore on passing from the point a to the point u_0 the entropy is decreased. But

since the adiabatic corresponds to zero entropy, the entropy should increase under these conditions. It follows therefore that the adiabatic must pass through u_0 , or a substance or mixture in the condensed state in contact with its vapor at the absolute zero of temperature corresponds to a state on the adiabatic of zero entropy. We may therefore take this state to correspond to zero entropy. This zero, which is the same as that of the internal energy, will for convenience be called the absolute zero of control.

The possibility that the substance may exist in several different (crystalline) forms at the absolute zero of control which possess different internal energies and entropies, remains to be considered. Suppose that two such forms are mixed at the absolute zero of temperature. The change Δu in internal energy is given by the thermodynamical equation

$$\Delta u = T \frac{dW}{dT} - W$$

where W denotes the external work done during the process of mixing. This may be carried out by allowing both forms to evaporate, mixing the resultant gases, and condensing the mixture. It will now be clear that the work done may be expressed in the form ΔAT , where A is a constant. Hence when $T = 0$ it follows from the above equation that $\Delta u = 0$, or no change in internal energy takes place on mixing. Thus the two forms have the same internal energy, which is zero.

It can be shown that a similar result holds for the entropy. The change in internal energy during an adiabatic change is given by

$$\left(\frac{\partial u}{\partial v}\right)_s = -p$$

which may be written

$$\left(\frac{\partial u}{\partial v}\right)_s = \left(\frac{\partial u}{\partial v}\right)_T - T \left(\frac{\partial p}{\partial T}\right)_v$$

by means of equation (3). At the absolute zero of temperature for any state this equation becomes

$$\left(\frac{\partial u}{\partial v}\right)_s = \left(\frac{\partial u}{\partial v}\right)_T$$

It expresses that as we pass isothermally from one form of the substance to another no change in entropy takes place.¹

Since the results of this Section are based on thermodynamics, deductions made from them will not apply to substances which cannot be passed through any conceivable thermodynamical cycle. They would therefore probably not apply to such a substance as glass, which, if evaporated and condensed again, is hardly likely to be in the same state as before, i.e., glass. A supercooled liquid probably does not admit of being passed through a cycle, at least in some cases, and to them these restrictions will therefore also apply.

¹ This proof is not quite satisfactory, but will have to suffice here. A better proof will be given in a subsequent paper.

A number of relations corresponding to the zero of control may be found by the help of the postulates of the next Section.

6. *The Differential Coefficients $\left(\frac{\partial u}{\partial v}\right)_T$, $\left(\frac{\partial u}{\partial T}\right)_v$, and $\left(\frac{\partial S}{\partial v}\right)_T$, $\left(\frac{\partial S}{\partial T}\right)_v$ are continuous for all Possible States of a Homogeneous Mass of Matter.*

An atom in a substance is in equilibrium under the influence of the forces of attraction and repulsion of the surrounding atoms. If these forces are not discontinuous for certain distances from their sources the above postulates would evidently hold. There does not seem to be any evidence whatever in nature of the existence of such discontinuities.

7. *Some Relations at the Absolute Zero of Control.*

Since the zero of internal energy corresponds to the least value it can have and $\left(\frac{\partial u}{\partial v}\right)_T$ and $\left(\frac{\partial u}{\partial T}\right)_v$ are not discontinuous, it follows from the Differential Calculus that the zero satisfies the conditions for a minimum, and hence we will have:

$$\left(\frac{\partial u}{\partial v}\right)_T = 0 \quad (5)$$

$$\left(\frac{\partial u}{\partial T}\right)_v = 0 \quad (6)$$

$$\frac{\partial^2 u}{\partial T^2} \frac{\partial^2 u}{\partial v^2} - \left(\frac{\partial^2 u}{\partial v \cdot \partial T}\right)^2 > 0 \quad (a)$$

$$\frac{\partial^2 u}{\partial v^2} > 0 \quad (b)$$

$$\frac{\partial^2 u}{\partial T^2} > 0 \quad (c)$$

A similar set of equations and inequalities hold for the entropy at the absolute zero of control. Since at this state the entropy has the least possible value, and $\left(\frac{\partial S}{\partial v}\right)_T$ and $\left(\frac{\partial S}{\partial T}\right)_v$ are not discontinuous according to the postulates in the preceding Section, it follows that the entropy satisfies the conditions of a minimum, and hence we have:

$$\left(\frac{\partial S}{\partial v}\right)_T = 0 \quad (7)$$

$$\left(\frac{\partial S}{\partial T}\right)_v = 0 \quad (8)$$

$$\frac{\partial S^2}{\partial T^2} \frac{\partial S^2}{\partial v^2} - \left(\frac{\partial^2 S}{\partial v \cdot \partial T} \right)^2 > 0 \quad (d)$$

$$\frac{\partial S^2}{\partial v^2} > 0 \quad (e)$$

$$\frac{\partial^2 S}{\partial T^2} > 0 \quad (f)$$

Equation (6) expresses that the specific heat of a substance or mixture in the condensed state kept at constant volume is zero at the absolute zero of temperature. This result is part of Nernst's theorem.

A formula for the specific heat of a substance in the gaseous state at infinite volume may be found which expresses an important property of this quantity. On multiplying equation (3) by ∂v and integrating it between the limits α and v it becomes

$$u_\alpha - u = \int_v^\alpha \left\{ T \left(\frac{\partial p}{\partial T} \right)_v - p \right\} \partial v \quad (9)$$

where u_α denotes the internal energy of the substances at infinite volume. Let us suppose that we are dealing with a mixture whose equation of state may be expanded in the form

$$p = \frac{ART}{v} + \frac{B}{v^\alpha} + \frac{C}{v^\beta} + \dots$$

where A is a constant, B, C, \dots functions of T , and α, β, \dots positive constants whose values are greater than unity. According to our experience this is likely to be always possible. The integral in equation (9) corresponding to the upper limit would accordingly be zero. On differentiating the equation with respect to T at constant volume we have

$$C_v = C_{v\alpha} + T \int \left(\frac{\partial^2 p}{\partial T^2} \right)_v \cdot \partial v \quad (10)$$

where C_v denotes the specific heat at the volume v , and $C_{v\alpha}$ that at infinite volume with the matter in the gaseous state. This equation applies to matter in any state. On applying it to a substance at the absolute zero of control

the integral will not become infinite since $\left(\frac{\partial^2 p}{\partial T^2} \right)_v$ is not infinite according to

the postulates in Section 3, and the volume has the finite value v_0 . The integral term therefore becomes zero, since $T = 0$. Since we also have $C_v = 0$ the equation gives

$$C_{v\alpha} = 0 \quad (11)$$

or the specific heat of a gas at constant infinite volume is zero at the absolute zero of temperature.

This is an interesting and important result, and is especially striking when a non-atomic gas is considered. Evidence of its truth already exists. Scheele and Heuse¹ have measured the specific heat of helium at various temperatures and found that it decreased though slightly with decrease of temperature. Thus for example at the temperatures 18°C and -180°C the specific heats were found to have the values 3.008 and 2.949 respectively.

The explanation of the result is probably that though the atom absorbs energy on increase of temperature due to an increase in the kinetic energy of translation, energy is also given out due to internal changes in the atom. These two changes balance each other at and near the absolute zero of temperature, or if $-u$ denotes the heat given out per gram molecule by the molecules from their internal controllable source of energy per unit increase in temperature, and $\frac{3}{2} R$ the heat absorbed through the increase in kinetic energy of motion of translation, we would have

$$\frac{3}{2} R - u = 0 \quad (12)$$

at the absolute zero of temperature. It should be noted in this connection that the internal energy of a number of molecules in the gaseous state at the absolute zero of temperature is not zero according to Section 4.

It appears from this explanation of the specific heat of a gas at the absolute zero of temperature, that it is not necessarily associated with a deviation from the gas laws, or the gas laws may hold for all temperatures. It is not impossible of course that the correct explanation is a different one than the foregoing, though at present it seems the most plausible.

It should be mentioned that Nernst² has deduced a formula for the decrease of the specific heat of a gas with decrease of temperature from a given theory of the atomic model and quantum considerations.

Formulae for the controllable internal energy and entropy of a substance or mixture may immediately be deduced corresponding to the volume v and absolute temperature T . Suppose that a substance or mixture at the absolute zero of control has its temperature raised to T keeping its volume v_0 constant.

The change in internal energy is equal to $\int_0^T C_v \cdot \partial T$, where C_v denotes the

specific heat corresponding to the constant volume v_0 . Next suppose that the volume is changed to v at constant temperature. The change in internal

energy is $\int_{v_0}^v \partial u$. The total change in internal energy, which is the controllable

internal energy u of the substance, is therefore given by

$$u = \int_0^T C_v \cdot \partial T + \int_{v_0}^v \partial u \quad (13)$$

¹ Ann. Physik, (4) 40, 484 (1913).

² Ber. deutsch. physik. Ges., 18, 85-116 (1916).

On substituting for ∂u from equation (3) and for C_v from equation (10) applied to the substance at the volume v_0 , in the foregoing equation, it becomes

$$u = \int_0^T \left[C_{v\alpha} + \int_{v=v_0}^v T \left(\frac{\partial p}{\partial T} \right)_v \partial v \right] \partial T + \int_{v_0}^v \left\{ T \left(\frac{\partial p}{\partial T} \right)_v - p \right\} \partial v \quad (14)$$

The expression for the entropy S obtained along the same lines is given by

$$S = \int_0^T \left[\frac{C_{v\alpha}}{T} + \int_{v=v_0}^v \left(\frac{\partial p}{\partial T} \right)_v \partial v \right] \partial T + \int_{v_0}^v \left(\frac{\partial p}{\partial T} \right)_v \partial v \quad (15)$$

The value of v_0 is given by

$$v_0 = 2.6 \Sigma N_w \sqrt{a_w} \quad (16)$$

according to Traube¹, where N_w denotes the number of gram atoms of atoms of atomic weight a_w relative to the hydrogen atom the substance contains. Thus if the equation of state of the substance or mixture and the specific heat $C_{v\alpha}$ be known the controllable internal energy and entropy may immediately be evaluated. Any empirical equation of state may be used provided its constants are determined from the facts. The controllable free energy F and the controllable thermodynamical potential Φ may then be obtained from the equations

$$F = u - TS \quad (17)$$

$$\Phi = u - TS + pv \quad (18)$$

It will be found that in all thermodynamical formulae useful for calculation we may substitute the controllable internal energy, entropy, free energy, and potential since the uncontrollable parts would disappear through differentiation or otherwise.

A number of other important formulae may be derived which will be given in a subsequent paper.

THE SYSTEM WATER-PHENOL*

BY JOHN BRIGHT FERGUSON¹

The system water-phenol is frequently cited as an example of a system in which two liquid phases occur. Such systems are of unusual interest since they provide a knotty problem for the proponents of the various theories which deal with "Solubility". The data dealing with such systems are unfortunately not very extensive and we have therefore endeavoured to supplement it by a number of calorimetric and vapour pressure measurements. The results of our experimental work together with a discussion of the available data are given in the following paper.

Part I. Specific Heats

The materials employed were distilled water and redistilled, Kahlbaum's synthetic C. P. phenol, melting point² 40.8°C. The solutions were made up by weight. The calorimeter proper consisted of a 250 cc small-mouth Dewar flask. It contained a glass-enclosed constantan-wire electric heater which had a resistance of 26.07 ohms, one end of a glass-enclosed, twelve-junction copper-constantan thermel and a rotary stirrer. The top of the flask was fitted with a rubber stopper which in turn fitted tightly the cases of the heater and thermometer and also the long glass bearing of the stirrer. The bearing was sealed and lubricated by a special very heavy rubber lubricant. The flask stood in a well-controlled air bath which in turn was inside a larger air bath. A similar Dewar flask was immersed in a water thermostat which was placed in the larger air bath. This flask contained the cold junctions of the calorimetric thermometer and one end of a reference thermometer of six junctions the other end of which was placed in an ice bath. This cold junction flask was provided with a rubber stopper having four holes. Two of these were for the cases of the thermometers and the other two for removable glass plugs. When these plugs were removed, a pipette was inserted in one hole and the bath water drawn into the flask. The flask contained no stirring device but all the available space was filled with strips of copper foil which extended the length of the flask.

The thermels were calibrated at the following points:

- (a) B. P. water.
- (b) Tr.³ $\text{SrCl}_2 \cdot 6\text{H}_2\text{O}$, 61.341°C.
- (c) Tr.⁴ $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$, 32.384°C.

⁴ Dickenson and Mueller: J. Am. Chem. Soc., 29, 1381 (1907).

The heating current was obtained from a set of storage batteries. A precision potentiometer was used both to measure the temperatures and also to check the heating current by determining the drop of potential across a known resistance.

With attention to details, the reference temperature bath was found satisfactory. In one case, two hours after changing the water, the bath temperature fell 0.0033°C in ten minutes. The change of temperature was in all cases regular and could be followed by means of the reference thermometer. The actual temperature of the reference bath was adjusted so that in any experiment it was just below the lowest temperature attained by the calorimeter.

The cooling or heating corrections were from 3 to 4 percent of the total heat supplied in experiments in which the actual heating took place in about 10 minutes. The calorimeter was calibrated using distilled water and in two experiments with cooling corrections, values of 14.76 and 14.96 cal. were obtained. An experiment in which a heating correction was necessary gave a value of 14.47 cal. The value of 14.73 cal. was used for the temperature interval 70° to 74°C . The heat usually supplied was 320 cal.

The results of these experiments¹ are given in Table I.

TABLE I
The Mean Specific Heats of Water-Phenol Solutions for the
Temperature Interval 70° to 74°

Composition Wt. percent Phenol	Temperature Interval De g. C.	Specific Heat calories*
0.00		1,001 (assumed value)
20.04	1,746 1,741	0,9350 0,9396
40.15	1,823 1,660	0,8640 0,8648
60.02	2,018 1,833	0,7597 0,7633
79.9	2,105	0,6545
100.0	2,117 1,782	0,5486 0,5487

* 1 calorie = 4.182 joules.

These results show a slight positive deviation from a straight line relationship and the point of maximum deviation is, approximately, at the consolute composition.

The specific heat of phenol has been previously determined by Schlamp² who obtained a value of 0.561 for the temperature 93.9°C .

¹ In the summary of this work previously reported, the composition 20.04 wt. percent phenol was erroneously given as 23.04 percent.

² Schlamp: Ber. oberhess. Ges. f. Nat. u Heilk., 31, 100 (1895).

Part II. The Heats of Mixing

The apparatus described in the preceding section was in the main used in the following experiments. A new calorimeter was however necessary. The one liquid was placed in a Dewar flask and the other liquid in a glass container which was immersed in the first liquid when in use. Stirring was obtained by rotating the glass container. The mixing occurred when two glass plugs were removed from openings in this container. One opening was

FIG. 1

The heat absorbed in the formation of water-phenol solutions at 71° C.

at the bottom centre and the other at the top on one side. When the plugs were removed the rotation gave rise to complete mixing due in part to centrifugal action. The heat capacity of this calorimeter was 26.05 ± 0.4 cal. The cooling or heating corrections were about one percent of the total heat quantity in most of the experiments. The volume capacity of the inner container was 25 cc so that differential measurements were necessary. Two series of experiments were carried out. In one series, the water was added to the phenol or to a solution and in the other the phenol was added to water or a solution. The results of these experiments, which were carried out at approximately 71°C and calculated to this temperature, are given in Table II and a graph of them is shown in Fig. 1.

Part III. Vapour Tension Measurements

Schreinemakers¹ has determined the vapour pressures of solutions of phenol and water. His values are unfortunately not very exact. Our own experiments were designed primarily to check certain of his results.

The tensimeter consisted of two glass bulbs connected by a U tube which contained mercury. When in use the bulbs were immersed in a water bath and the emergent glass tubes were heated electrically to prevent condensation. The chief difficulty encountered was that of freeing the liquids of air. This was accomplished by heating the liquids above the critical temperature between evacuations and shaking violently. We could not remove the air from the phenol rich layer at room temperature by repeated evacuations and agitation in any reasonable time. After each experiment the solutions were analysed using Lloyd's method.² Water was used as an initial reference material and for it a vapour pressure of 289,1 mm was assumed.

Our results are given in Table III.

Especial care was taken with the differential measurements of the 23,33 and 46,81 percent solutions. There can be no question but that the vapour tensions of these solutions do not differ by more than 0,2 mm. Our results confirm the earlier work of Schreinemakers though the actual pressure given by him for these solutions is 294 mm.

23,33	290,2		289,25

Part IV. Thermodynamics¹

The unaccented symbols refer to a liquid phase at a temperature θ deg. K. and at atmospheric pressure while the accented symbols refer to the same phase at the same pressure but at a new temperature θ' . The specific heats are assumed to be independent of the temperature.

$$\bar{z} = \bar{x} - \theta \bar{\eta}$$

$$\bar{z}' = x' - \theta' \bar{\eta}' = \bar{x} - \bar{c} (\theta - \theta') - \theta' \left(\bar{\eta} - c \log_{\theta} \frac{\theta}{\theta'} \right)$$

Hence:—

$$\bar{z}' = \frac{\theta'}{\theta} \bar{z} + \frac{\theta - \theta'}{\theta} \bar{x} - \bar{c} \left\{ (\theta - \theta') - \theta' \log_{\theta} \frac{\theta}{\theta'} \right\} \quad 1$$

and

$$\frac{D^2 \bar{z}'}{Dx^2} = \frac{\theta'}{\theta} \frac{D^2 \bar{z}}{Dx^2} + \frac{\theta - \theta'}{\theta} \frac{D^2 \bar{x}}{Dx^2} - \left\{ \theta - \theta' - \theta' \log_{\theta} \frac{\theta}{\theta'} \right\} \frac{D^2 \bar{c}}{Dx^2} \quad II$$

Equation I defines the zeta for one temperature in terms of the zeta and chi for another temperature, the specific heat and the two temperatures. If we restrict this equation to systems of two components, x and y , and differentiate twice in respect to x , ($x+y=1$), we obtain equation II. The first term of this equation is positive for all stable phases, negative for all unstable phases and zero for critical phases.

For the system water-phenol we can evaluate the first and second terms of equation II from the thermal data alone if we restrict ourselves to the consolute composition. The latter is approximately 34 wt. percent phenol and the consolute temperature² for *pure* phenol and water is 339 deg. K. For term two (344.1 deg. K), we obtain 0.1022 and for term one (338.1 and 333.1 deg. K) respectively -0.0085 and -0.0054. The positive sign for the stable phase is certainly established but the negative signs, while obtained, are somewhat uncertain owing to the size of the quantities involved. However if one could find a similar system in which the last two terms have the same numerical sign, the negative sign for the unstable phase would be established without a numerical calculation.

¹ For a discussion of symbols, see W. Lash Miller: Chem. Rev., 1, 294 (1924-5).

² Hill and Malisoff: J. Am. Chem. Soc., 48, 922 (1926).

From equation II, the tendency for any solution to split into two layers on changing the temperature is a function of the zeta and chi of the stable solution and of the specific heats. The function is however such that this change is unlikely when the zeta curve for the stable solutions at a temperature which is near their respective dissolution temperatures deviates much from a straight line. For the simple case in which the vapour may be considered as a perfect gaseous solution this statement may be interpreted in terms of the total and partial pressures in the following manner. The zeta for a liquid containing one formula weight of the components is given by the equation:

FIG. 2

The partial and total vapour pressures of water-phenol solutions at 75° C.

$$z = R\theta + n_1 R\theta \log_{\pi} \frac{\pi_1}{p_1} + n_2 R\theta \log_{\pi} \frac{\pi_2}{p_2} \quad (n_1 + n_2 = 1) \quad \text{III}$$

in which R is the gas constant, θ the temperature deg. K., π_1 and π_2 the partial vapour pressures and p_1 and p_2 the vapour pressures of the components in the reference states. In each case the reference state is taken as the saturated vapour of the component at θ deg. K. and for these states ϵ and η are given zero values. If this equation be differentiated, keeping in mind the approximate equation of Duhem-Margules, we obtain

$$\frac{D^2 z}{Dn_1^2} = \frac{R\theta}{n_2} \cdot \frac{1}{\pi_1} \cdot \frac{D\pi_1}{Dn_1} \quad \text{IV}$$

from which it follows that for the zeta curve to approximate a straight line the partial pressure curve for the one component must have a nearly horizontal position parallel to the composition axis.¹ The total pressure will also have a similar curve.

These relations are approximately obeyed by the system under discussion as shown by Fig. 2. The partial pressures were calculated from the results of Scheinemakers and ourselves on the solutions and the work of Kahlbaum² on pure phenol, upon the assumption that the vapours were perfect gases. The consolute composition is approximately nine mols percent phenol.

For the very dilute solutions of phenol the partial pressure for water appears to obey Raoult's Law. The maximum deviation occurs at about 40 mols percent phenol and this is the approximate composition showing the maximum heat of mixing. On plotting the differential heats of mixing obtained by the method of intercepts, the curve for water is convex toward the composition axis as it approaches its origin which is in agreement with the partial pressures of the dilute solutions.

In conclusion, we wish to thank Prof. Lash Miller, Prof. W. S. Funnell and Mr. H. B. Hope for their assistance.

Summary

1. The specific heats of solutions of phenol and water have been determined at 70-74 deg. C.
2. The heats of formation of these solutions have been measured at approximately 71 deg. C.
3. The vapour tensions of a limited number of solutions were observed at 75 deg. C.
4. A thermodynamical study of the available data has been made.

Toronto, Canada.
January 10, 1927.

¹ Although equation II is on a one-gram basis while equation IV is on a one formula weight basis, this does not materially affect the conclusion.

THE LIGHT-SCATTERING CAPACITY (TYNDALL EFFECT) AND COLLOIDAL BEHAVIOUR OF GELATIN SOLS AND GELS*

BY ELMER O. KRAEMER** AND STEPHEN T. DEXTER***

One of the characteristic properties of disperse or colloidal systems is the Faraday-Tyndall effect, i.e., the capacity of such systems, when illuminated unilaterally, to scatter light in all directions. According to Rayleigh, the relative intensity of the light scattered at right angles to the axis of illumination by dilute sols of constant volume concentration, containing very small non-conducting particles, is given by the equation

$$I = \frac{kv}{\lambda^4} \left(\frac{n_1^2 - n^2}{n_1^2 + 2n^2} \right)^2$$

in which k is a constant of proportionality; v , the mean volume of the particles; λ , the wave length of the light used; and n_1 and n are the indices of refraction of disperse phase and medium respectively. With a given system, for which n_1 and n are constant, the intensity of the tyndall effect is directly proportional to the mean volume of the particles. The condition and changes of dispersion of a system are therefore directly revealed in the tyndall effect.

Very little attention has thus far been given to the significance of this property in connection with the problems associated with the colloidal behaviour of the proteins. Qualitative observations, it is true, have been made of superficial turbidities. The most important of these for gelatin systems are due to Dhéré and Gorgolewski¹ who noted the great increase in turbidity or opacity of gelatin sols as the ash content was decreased. Using purified and de-ashed gelatin in dilute systems, they described the disappearance of the turbidity above 30°C and observed the very small concentrations of acids or bases sufficient to remove the turbidity at temperatures below 30°C. Neutral salts were found to be relatively much less effective for this purpose. They first clearly described the increase in turbidity to a maximum and subsequent decrease as the concentration of the gelatin gels increased. The maximum turbidity was found to occur at approximately 2.5 percent; 10 percent gelatin gels were as free from superficial turbidity as 0.5 to 1 percent systems. At low temperatures, they further observed that the gelatin tended to precipitate out from dilute systems. These studies were probably the first to be made upon highly de-ashed gelatin (less than 0.1 percent ash).

Somewhat later, Arisz² recorded photographically the tyndall effects of gelatin systems in a mixed glycerine-water solvent. In spite of the complications due to ash content and mixed solvent, Arisz observed much the same

behaviour as Dhéré and Gorgolewski had recorded. Subsequent workers, in increasing number, have confirmed in a qualitative way the earlier observations on the influence of acids, bases, temperature, gelatin concentration, and purity upon the turbidity of aqueous gelatin systems. As the theory of ampholytes was applied to the behaviour of proteins in aqueous systems, the maximum turbidity became identified with the "isoelectric point," and was used in determining the H ion activity associated with this state.

The first investigation, however, of the colloidal behaviour of aqueous gelatin systems under various conditions by means of *quantitative* studies of the light-scattering capacity appeared but recently. In a paper on the optical activity of gelatin systems¹, the present authors gave a curve showing the relationship at 24°C between relative intensity of scattered light and the pH of one percent de-ashed gelatin systems. It was found that a sharp rise in tyndall intensity took place at the isoelectric point, quantitatively confirming the observations of Dhéré. Within a fraction of a pH unit, the increase exceeded 1000 percent. The maximum intensity located the isoelectric point with greater certainty and exactness than perhaps any other property of the system. About the same time, a similar curve, but inadequately defined, was published by Vlès and Vellinger.² On account of the paucity of data, their curve did not show the abrupt rise in tyndall effect described above.

The application of this technic to aqueous gelatin systems has been continued. Upon the assumption that the maximum tyndall intensity locates the isoelectric point, an examination of gelatins of various sources has shown that the isoelectric points do not fall at a constant pH for all gelatins. For certain bone gelatins, values as high as pH 5.5 were found. This fluctuation in isoelectric point suggests either that "gelatin" consists of an unknown number of unknown chemical entities or that the isoelectric point of such material does not bear the relation to the chemical character of the material which is implied in the application of the theory of ampholytes to its behaviour. The first alternative seems fairly well established; the second is possible. Mixed gelatins, however, do not reveal themselves as such in the tyndall effect studies. It is probable that the differences in gelatins reflect differences in the gelatin precursors.

The light-scattering capacity and its dependence on pH and temperature is of significance in connection with questions concerning the condition of gelatin in the sol state. The new data suggest that the effectiveness of a trace of acid or base in preventing precipitation of gelatin from dilute systems near the isoelectric point is probably not simply a question of protective action due to electrical charge, for the actual cataphoretic mobility is known to remain undetectable with such small electrolyte concentrations. Nor is there any immediate way by which the effect of acids and bases on tyndall effect—and by inference, on degree of dispersion—may be quantitatively interpreted in terms of the theory of ampholyte solubility as it now stands. On the other

¹ Kraemer and Fanselow: J. Phys. Chem., 29, 1169 (1925).

² Vlès and Vellinger: Compt. rend., 181, 1189 (1925).

hand, the dispersion of gelatin by increasing temperatures, as revealed in terms of light-scattering capacity, does not so much resemble an increase in true solubility of a phase of constant composition in contact with its saturated solution. Rather, the process has features in common either with conjugate solutions passing the consolute temperature, or with disperse systems passing a critical peptization temperature. The elucidation of gelatin behaviour near the isoelectric point depends upon a proper recognition and evaluation of those phenomena describable in terms of chemical reactions and compounds, and of those commonly considered characteristic of colloidal or disperse systems. It is hoped that some of the vagueness and uncertainty now present will be removed upon completion of investigations concerning salt effects and light-scattering capacity.

Procedure

The relative light-scattering capacities of the gelatin sols and gels were measured by means of an improvised tyndallimeter. A beam of light from a 6 volt, 108 watt concentrated filament source was passed through a long column of water to remove heat rays, and split into two beams by a clear glass reflector. One beam passed through a series of apertures and illuminated the gelatin systems contained in 2 oz. square medicine bottles selected for uniformity. The light scattered by the gelatin at an angle of 90° to the axis of illumination, and the reflected portion of the original beam, after passing through neutral or colored screens, slits and two nicol prisms, were brought into juxtaposition for comparison by a Lummer-Brodhun photometric head. By means of appropriately chosen screens of known transmissions in the two beams and a proper rotation of one of the nicols, the relative intensity of the scattered light was determined in terms of the intensity of the illuminating beam.

The gelatins used were of various types and grades. As specified in each case, some were commercial gelatins containing ash, others were de-ashed by various processes. The gelatin sols were prepared in a uniform fashion. A stock solution sufficient in quantity for an entire series of observations was prepared in a concentration somewhat greater than that desired in the final samples by heating appropriate amounts of swollen gelatin and water at 60°C . for 20 minutes. To measured portions of this stock, appropriate quantities of water, dilute sodium hydroxide, or dilute hydrochloric acid were added to give sols of the desired pH with one gram of vacuum-dried gelatin in 100 cc of solution at 25°C . These specimens were kept at 60°C for 20 minutes to efface any effects of previous thermal history, and then transferred to the thermostat at the temperature of which the tyndall effect was to be observed. A trace of thymol, which produced no measurable effect upon the intensities of the scattered light, was commonly used as a preservative. H ion activities were determined with the H electrode and calomel cell chain at room temperatures, and confirmed by comparison with standard buffers.

The relative intensities of the scattered light were determined after constant values were attained at a given temperature. At temperatures of

30°C and higher, a constant intensity was attained practically as soon as thermal equilibrium. Between 17° and 30°C measurements were made after 24 hours; in the absence of salts, no further appreciable change was observed during the next 50 hours.

Isoelectric Points of Gelatins

In the application of the theory of ampholytes to protein behaviour, the pH of minimum solubility or maximum precipitation tendency in the absence of salts is said to locate the isoelectric point. This point, in the case of gelatin, may be located accurately and conveniently by determining the pH of maximum intensity of scattered light. The results of applying this method to a number of specimens of de-ashed and commercial gelatins follow.

De-ashed Gelatins: A comparison of the pH's starred with those in *italics* indicates that only those gelatins were in the isoelectric condition which had been electrodialedyzed in the gel state. The other gelatins (Eastman A, B, C, and ossein gelatin) all contained excess of acid or base. However, as shown by a comparison of Eastman A and A', removal of the excess acid did not change the pH of maximum intensity of the scattered light, but did increase the height and sharpness of the maximum. The same constancy in the position of maximum intensity was shown by the "Silver Label de-ashed" of Table I and the original gelatin containing 1.5 percent ash. Low temperature electrodialedysis as a de-ashing procedure therefore appeared to be without influence upon the isoelectric point of the gelatin; nor did the normal ash content in these cases cause any displacement of the pH of maximum intensity.

For the first five (hide) gelatins, the maximum intensity, and therefore presumably the isoelectric point, was located at practically a constant pH, 4.95-5.01, in spite of considerable differences in gel strength. For example, Eastman A and Eastman C showed essentially identical light-scattering capacities and identical isoelectric points. On the other hand, Eastman A formed stable gels at quite low concentrations, while Eastman C had the properties rather of a low grade gelatin. The data of the table demonstrate how sharply the maxima were located. It is, at the same time, evident that there is a distinct discrepancy between the position of the isoelectric points of these specimens and the value usually quoted for gelatin (pH 4.65-4.70).

A still greater discrepancy is furnished by the ossein gelatin I with its maximum light-scattering capacity and apparent isoelectric point at pH 5.5, i.e., at a H ion activity *less than one-third* as great as at the isoelectric points of the hide gelatins. It is also to be noted that the maximum was broader and flatter than was found with the hide gelatins. However, a third extraction of the ossein (ossein III) displayed a maximum intensity of scattered light near pH 4.9, with the hide gelatins. The maximum for ossein III was less abrupt and much less lofty than were the maxima for the hide gelatins. These variations and lack of uniqueness in gelatin behaviour are illustrated in greater detail by the observations on commercial gelatins which follow.

Commercial Hide and Bone Gelatins: Since, as was indicated above, the presence of ash in commercial Silver Label gelatin did not interfere with the

* Indicate the pH of one percent gelatin sols without added acid or alkali. Italics indicate the pH of maximum intensity of scattered light, and therefore, presumably, the pH of the isoelectric point within the limits of experimental error.

EASTMAN A and B: technical hide gelatins de-ashed by Eastman Kodak Co. by washing and precipitation of the gelatin.

EASTMAN C: technical hide gelatin de-ashed by protracted electro-dialysis of a molten gel and precipitation.

EASTMAN A': prepared by a further electrodialysis without membranes of a 10 percent gel of Eastman A at 5°C.

SILVER LABEL DE-ASHED: "Silver Label," a high-grade hide gelatin de-ashed by electro-dialysis of a gel at 5°C. This and the preceding specimen were kindly prepared by Dr. Ralph Mason.

OSSEIN GELATINS: prepared by Mr. J. R. Fanselow from purified ossein furnished by Hammond Organic Products Co. The ossein had been prepared by acid extraction of selected bones. It was treated with 0.2% sodium hydroxide for 3 months, changing the alkali every 3 days, to remove chondroitin-sulfuric acid, and other tissue impurities (Method of Knaggs and Schryver: *Biochem. J.*, 18, 1079 (1924)). From this ossein, well washed with distilled water, 3 gelatin specimens were prepared by heating at 60°, 70°, and 80°C. Ossein gelatin I was further washed in Loeb's way (Loeb: *J. Gen. Physiol.*, 1, 45 (1918)).

determination of the isoelectric point by the tyndallimetric method, it was assumed that other commercial gelatins might be studied in the same way. The data for room temperatures are presented in Figs. 1, 2, and 3. Fig. 1 refers to a series of calfskin gelatins, kindly furnished by the U. S. Gelatin Co., which were said to represent successive extractions of the same raw stock. In spite of considerable differences in quality and gel strength, the maximum light-scattering capacity, and presumably the isoelectric point, was practically constant at pH 4.9 to 5.0 for the entire series. In all cases, the light-scattering

capacity fell precipitously on each side of the maximum. Since the curves are almost discontinuous at the maxima, their exact heights cannot be determined; the maximum possible intensities therefore cannot be compared. However, the curves of Fig. 1 suggest the absence of any very striking differences in the maximum intensity for the five gelatins.

FIG. 1

Isoelectric points of successive extractions of calfskin gelatin stock as shown by the pH of maximum tyndall effect.

Fig. 2 presents observations on a series of Delft bone gelatins. Gelatins I-V were said to represent successive extractions of the purified bone stock, while gelatin VI was a special blended bone gelatin. Gelatin I, the highest grade member of the series, is seen to have resembled in its behaviour the "de-ashed ossein gelatin I" described earlier in this paper, for in both cases, the broad maximum fell near a pH 5.5. For succeeding members, the maximum intensity of scattered light shifted gradually toward pH 4.0 characteristic of the hide gelatins; at the same time, the height of the maxima fell decidedly. The ossein gelatins of Table I, it may be remembered, showed this same shift, a behaviour possibly characteristic of gelatin fractions from bone stock. These series of hide and bone gelatins might suggest that the two types could be distinguished by the character of these curves. This is shown to be erroneous by the striking resemblance between gelatin VI of the second group, described as a blended bone gelatin, and the hide gelatins of the first group with respect to the position of the maxima, although, it is true, the heights differ considerably.

The behaviour of other specimens is illustrated in Fig. 3 by data on three edible gelatins. "Cox" and "Knox" were blended gelatins of unknown com-

position and resemble the Delft blended bone gelatin. Of special interest is the pigskin gelatin with a maximum light-scattering capacity and isoelectric point (?) at the extreme pH of 8.

Gelatin Mixtures: In view of the probable heterogeneity of gelatins, it is of interest to examine the relationship between pH and light-scattering capacities of gelatin mixtures. One may wonder whether the components of a mixture would be revealed by the appearance of separate maxima in light-

scattering capacity corresponding to the separate isoelectric points, or whether the precipitation tendencies of the components would be mutually modified to give a single new maximum tyndall effect or apparent isoelectric point. Figs. 4, 5, and 6 present observations at room temperatures on various mixtures of the gelatins discussed above. In no case were double maxima observed for a mixture; the components of the mixture were not revealed by the relationship between light-scattering capacity and pH. In Fig. 4, it is

seen that in a 50 percent mixture, the lowest grade Delft bone gelatin (V) practically effaced any evidence for the existence of an equal quantity of the highest grade Delft gelatin (I) in the mixture. This dominance of one component was even more strikingly shown in mixtures of calf-skin (I) and Delft bone gelatin (I) for which data appear in Fig. 5. Even 10 percent of the hide gelatin sufficed to give a maximum light-scattering capacity at a pH near 5. The intensity of the scattered light at pH 5.5, corresponding to the maximum for 90 percent of the mixture, was relatively low. Similar relationships are shown in Fig. 6 for mixtures of calf-skin (I) and pig-skin gelatins. In each case, the influence of the component with a maximum tyndall effect near pH 5 is more marked in determining the properties of a mixture.

Discussion: Following Chiari's original estimation (not based on any actual pH measurement) of pH 4.7 for minimum swelling, the older values assigned to the isoelectric point of gelatin usually fell near pH 4.6-4.7. The earlier work implicitly suggests the assumption that all gelatins are characterized by a constant specific value for the isoelectric point, Table II.

Since at that time the attention was naturally focussed upon the determination of the type of change in properties of gelatin systems near the isoelectric point, no particular effort was made to test the constancy of the quantity for different gelatins, or to locate with exactness the value for a given specimen. The tendency was rather to locate the approximate pH associated with a maximum or minimum in a physical property, and to assign to the isoelectric point the numerical value used by previous investigators. In any case, on account of insufficiently detailed experimentation,¹ inconsistencies in pH determinations by various workers, and ill-defined maxima or minima obtainable with many properties², it was not possible to discriminate between values differing by less than several tenths of a pH unit (or 100 percent differences in H ion activity). This indefiniteness is made evident upon comparing columns C, D, and E. The range of uncertainty in column C is expressed in terms of actual experimental observations between which it is dangerous to interpolate, particularly unless it has been shown by detailed experimentation that multiple maxima or minima do not occur.³ In spite of these uncertainties, the differences between such experimental observations as are given in references 3c and 10—both by methods capable of locating the isoelectric point

¹ Illustrated by the range of uncertainty in references 3a, 3b, 4, 7b, 9, 14, and 23, of Table II.

² Illustrated in references 1, 2, 6, 11, and 23 of Table II.

³ Sudden changes from minima to maxima very near the isoelectric point are shown by the rate of ice crystallization (ref. 16, Fig. 4), relative resistance to shear, gel formation and optical rotation (ref. 21b). The confusion which may arise as a consequence is illustrated by Fig. 7 of reference 16 in which the minimum rate of ice crystallization at pH 4.4 does not locate the isoelectric point. It is probable that the apparent discrepancies in isoelectric points as located by gelation and by turbidity in reference 12 were the result of these sudden changes in behaviour near the isoelectric point. Contrary to the usual assumption (see ref. 11), it was shown in ref. 21b that the maximum gel formation and maximum turbidity do not coincide in dilute gelatin systems.

quite sharply—would appear to exceed the probable inconsistency in pH measurement and therefore to suggest an inconstancy in isoelectric point. These differences were not generally noted, and it remained for Gerngross and Bach to demonstrate, in an insufficiently recognized paper, that the isoelectric points of gelatins may vary by as much as a whole pH unit. They found, as summarized in the table, the isoelectric points of four de-ashed *bone* gelatins to fall at $\text{pH } 5.0 \pm 0.1$. On the other hand, three specially prepared and de-ashed *hide* gelatins possessed isoelectric points between pH 5.4 and 5.6. Eight commercial gelatins of unspecified source gave values between pH 4.45 and 5.05. Our data confirm the inconstancy in the isoelectric points of gelatins, suggesting even that it may extend to pH 8. There is however a curious and rather puzzling discrepancy. Whereas Gerngross and Bach found high values with hide gelatins, our high values were observed with bone gelatins.

Perhaps it should not seem surprising that the isoelectric points of gelatin vary. The inconstancy in chemical constitution has of course long been recognized. With the possible exception of some who have been particularly zealous in evaluating molecular weights, dissociation constants, and the like, students of gelatin systems have in general recognized the present impossibility of isolating and defining a unique chemical species in gelatin. This has been made clear by the careful work of Schryver¹ and his students, although much remains to be done in the fractionation and chemical characterization of the products of collagen or ossein "hydrolysis." The customary suggestion is that the lack of uniformity in properties of various gelatins may be due to the presence of a whole series of hydrolysis products between the original collagen and amino acids. And yet this suggestion is not an entirely satisfactory explanation of fluctuations in isoelectric point, for as Gerngross and Bach and others have shown, a given extraction or fraction of gelatin may be subjected to considerable hydrolysis without displacing the isoelectric point. In the presentation of the data of this paper, various of the hide gelatins were recognized as being of different grades, perhaps containing different quantities of hydrolysis products; but these differences were not accompanied by differences in isoelectric points. The available data give the impression that the isoelectric points fall into two groups, one near pH 5.5, the other near pH 4.9. Gelatin samples with maximum tyndall effects and isoelectric points between pH 5 and 5.5 may be mixtures of components corresponding to these two groups, which are not revealed individually, as illustrated by the data on mixtures in this paper. It is of interest and may be of significance that discontinuities appear to fall at the same pH's in the properties of gelatin precursors.² It thus seems possible that the fluctuations in the isoelectric points of gelatins may indicate inherent heterogeneities of some type in the gelatin precursors rather than be due to different degrees of hydrolysis.

¹ Schryver et al: *Biochem. J.*, **15**, **17**, **18** (1921-1924).

² Porter: *J. Soc. Leather Trades' Chem.*, **5**, 259 (1921); Thomas and Kelly: *J. Am. Chem. Soc.*, **44**, 195 (1922); *J. Ind. Eng. Chem.*, **15**, 1148; Wilson and Gallun: **71** (1923); Meunier, Chambard and Jamet: *J. Intern. Leather Tr. Chem.*, **9**, 200 (1925). Discontinuities have also been found at pH 8 by Wilson and Daub: *J. Ind. Eng. Chem.*, **13**, 1137 (1921).

As one possibility, the gelatin precursor may consist of two or more separate and distinct chemical entities which upon "hydrolysis" may yield gelatins with different properties and isoelectric points. Or, as another possibility, the gelatin precursor may possess structural (rather than simple chemical) heterogeneities of the type shown by Odén's sulfur and certain silver sols.¹ These systems are peculiar in that the quantity of "peptizing" agent required to give them stability in the sol condition varies with the degree of dispersion of the dispersed phase. The analogy suggests that different fractions of gelatin from given stock may be very nearly identical chemically and yet require varying acidities in the isoelectric condition. In either case, the isoelectric points of gelatins would depend upon the *characteristics of the precursors*. Elucidation of the cause for fluctuations in isoelectric point probably involves the problem of gelatin formation. At the present time, the choice between "hydrolysis" explanations and "peptization" explanations is largely a matter of personal preference. Both views are equally vague. Regardless of the mechanism of gelatin formation, the heterogeneity of many gelatins can scarcely be doubted.² As a consequence, the detailed interpretation of those aspects of gelatin behaviour to which it seems reasonable to apply the theory of ampholytes becomes a very difficult problem.

Influence of pH and Temperature upon the Light-Scattering Capacity of De-aired Gelatin Systems

The sol-gel transformation of gelatin systems with change of temperature is an important and characteristic feature of their colloidal behaviour. Since it seems probable that gel formation is intimately associated with changes tending to precipitate formation³, the relationship between sol-gel transformations and light-scattering capacities might be expected to be rather direct.

One aspect of these relationships is presented in Fig. 7, showing the dependence of light-scattering capacity upon H ion activity and temperature for gelatin systems containing, at 25°C, 1 g. vacuum dried gelatin (Eastman A, above) in 100 cc of solution. At temperatures of 40-50°C, where the gelatin was in a sol state, the light-scattering capacity was not great and was almost independent of temperature and pH. Only a relatively slight rise in intensity occurred in the neighborhood of pH 5. At these temperatures, a constant intensity of scattered light was attained practically as soon as thermal equilibrium. At lower temperatures, which bring about gel formation, there suddenly appeared an extremely pronounced maximum at a pH 4.95, the isoelectric point of the gelatin. In the range studied (pH 2.5-12.), this increase in tyndall effect was limited to the region between pH 4.5 and 7.5. Below pH 4.5 and above pH 7.5, a decrease in temperature from 50 to 17°C left the light-scattering capacity practically unchanged. The general form

of the curve is asymmetrical. On the basic side of the isoelectric point, the influence of temperature appears somewhat more extended. The asymmetry is due in part to the use of pH notation (a logarithmic one), in part to the nature of the gelatin systems, for the same asymmetry in various degrees is shown by most other properties.

4.66	1.84	8.30	0.89	12.10	0.21
4.79	2.21	9.12	0.71	12.22	0.19
4.87	2.59				

The abruptness with which the tyndall effect increases between 30° and 17°C is particularly striking. As may be seen in Table III, the relative intensity of scattered light increases about 430 percent for a change in pH but little greater than experimental error (4.87-4.90). Only 0.1 cc of 0.1 N hydrochloric acid was required to lower the intensity of 100 cc of a 1 percent isoelectric sol by 90 percent of the excess over the value, constant with temperature, at pH 4.65. After an increase in the height of the maximum by electro dialysis (Table I), the same quantity of acid gave rise to an even steeper drop. Since ca. 9 cc of acid were combined with 1 g. of gelatin at pH 1.7, usually considered as the point of complete combination, it is evident that only 1/90 or approximately one percent of the total combining capacity of the gelatin was involved in converting the gelatin from the "insoluble" isoelectric form to the sol condition. Four times this quantity of acid suffices to transform the gelatin to a form (at pH 4.65) in which the light-scattering capacity is practically independent of temperature. The dependence of tyndall intensity upon pH therefore does not parallel the combination curve for gelatin, but does resemble the rapid decrease in ease of precipitation with alcohol as the pH decreases from the isoelectric point.¹

Discussion: In terms of the components of the systems, it appears that, in the sol state above 30°C, the solution units or gelatin micells are well defined and highly dispersed. Changes in equilibria, as a result of either pH or temperature change, take place rapidly and without hysteresis. Under all conditions of temperature or of combination with acid or base, the solution units possess a low absolute light-scattering capacity equal in order of magnitude to what one might expect in a dispersion of huge molecules. However, whether the solution units or micells above 30°C are uniform chemical molecules of gelatin or not is a question not to be answered dogmatically. To the extent that the light-scattering capacity above 30°C is constant with change of pH, it may be assumed as a first approximation that the size of the micells and their relative index of refraction, with respect to the solvent, is constant in order of magnitude. Since it seems improbable that decrease in temperature should greatly modify the relative index of refraction of the gelatin micells², the increase in light-scattering capacity at lower temperatures and near pH 5 may tentatively be supposed to indicate an increase in size of micells. In accordance with Rayleigh's formula, the relative intensity of scattered light for small particles at constant total concentration is proportional to the mean particle-volume. The tyndall effect curves therefore give an approximate picture of the variation in size (volume) of the gelatin micells.

Just at the isoelectric point, it is obvious from the superficial turbidity that the increase in size of micells has reached the advanced stage of gross

¹ Loeb: J. Gen. Physiol., 3, 257 (1919); Pauli: "Colloid Chemistry of the Proteins", p. 46 (1922).

² The partial specific volume of gelatin shows no discontinuity, but changes gradually and normally with temperature. Cf. Taffel: J. Chem. Soc., 121, 1971 (1922), and Davis and Oakes: J. Am. Chem. Soc., 44, 464 (1922). It is therefore also probable that any chemical hydration which can be concretely conceived should not vary greatly with moderate temperature changes. Loosely bound water vaguely referred to as hydration, if any, might be expected to serve as part of the medium with respect to the scattering of light.

precipitation for which Rayleigh's formula is invalid. The discontinuity in light-scattering capacity is so sharp, however, that there is no necessity or advantage in attempting to apply the formula to the vertical portions of the curves. It is sufficient to point out that over a very narrow range of pH, the size of the gelatin micells shows a remarkable sensitivity to small quantities of acid or base. If dispersion of 1 gram of "insoluble" isoelectric gelatin into low light-scattering micells takes place by union of but one molecule hydrochloric acid per micell, the average equivalent aggregate weight at pH 4.87 (requiring 0.1 cc 0.1 N acid) must be 100,000.¹ As a compact cube of partial specific volume equal to 0.67,² such a micell would measure almost 5 millimicrons on an edge—a very large unit to be held in the sol state by a single molecule of hydrochloric acid. Complete saturation of such a micell with acid (in the ordinary sense, i.e., 9 cc 0.1 N acid per gram of gelatin at pH 1.7-2.0) would require 90 equivalents of acid and involve evaluating 90 specific basic dissociation constants to characterize the micell as a base.

Without taking such estimations too seriously, one may yet readily recognize that the abruptness with which a trace of acid is able to convert the insoluble isoelectric gelatin into the sol state³ is not to be coordinated with the simple theory of the solubility of ampholytes.⁴ The mechanism of the process is shrouded in the general uncertainty surrounding the behaviour of gelatin at the isoelectric point. Harris, for example, suggests an extensive formation of zwitterions at the isoelectric point⁵, and Modern and Pauli present evidence indicating that the hydrochloride formed with gelatin just adjacent to the isoelectric point is relatively slightly ionized.⁶ This chemical complexity resembles that to be met in the stabilization by electrolytes of many well-defined disperse systems. Therefore, until greater clarity is attained, it seems preferable to apply tentatively the frankly noncommittal term "peptization" to both cases.

Besides the mechanism of sol formation by acid or base, the mechanism of the change at the isoelectric point as the temperature is raised, is but vaguely understood. From the curves of light-scattering capacity, it is clear that, as the temperature is raised, a significant change takes place in the temperature range 23°-30°C. Below these temperatures, a vanishingly small quantity of gelatin goes spontaneously into the sol state.⁷ Above this temperature range, it is common experience that almost unlimited amounts of gelatin are dispersed spontaneously to give a sol of low light-scattering capac-

ity, with some shift in the temperature range at high concentrations¹. It is at present not possible to place definitely this phenomenon in the general classification of temperature displacement of equilibria. Some describe the case of gelatin in terms of the variation in true solubility of a homogeneous solid phase with temperature.² But a large temperature coefficient of solubility would be associated, according to van't Hoff's equation, with a large heat of solution of swollen gelatin. Such has never been observed.

On the other hand, it may be pertinent to analyze the peptization of iso-electric gelatin with increase of temperature and the critical solution phenomena from a common point of view.³ In both cases, two phases of variable composition blend at a sufficiently high temperature to give one essentially homogeneous phase. Unfortunately for the gelatin case, the "critical solution temperature" is not sharply defined nor entirely independent of composition of the system. Such a situation could, however, conceivably arise if the gelatin contained a number of components of varying critical solution temperature which mutually interfered.

A third attempt at classification of gelatin behaviour might be made by comparing and aligning it with the equally striking behaviour of certain sulfur sols.⁴ Although clearly heterogeneous, these sulfur sols in contact with coagulum behave very much like an ordinary saturated solution in contact with its solid crystalline phase. In gelatin sols and sulfur sols, an entirely reversible temperature equilibrium is displayed, as well as the abruptness of the temperature effect. In both cases, the abruptness increases with the extent of "purification." In the sulfur sols the ease of dispersion is greater for small particles, and appropriate methods of "purification" (i.e. fractional coagulation) yield a product with a relatively uniform size of particle and a surprisingly sharp critical peptization temperature. Superficially at least, the same observable effects follow the careful purification of gelatins. It is not at all impossible that the heterogeneity of gelatin systems may be not only chemical but also one of non-uniformity in size of particle (if this be the correct interpretation of the sulfur sol). Furthermore, it seems possible that a similar parallelism exists between sulfur sols and casein⁵ or globulin⁶ systems.

In spite of the attractiveness of the third case, it is scarcely possible to make a choice with certainty of success. The completion of the investigation of salt effects and light-scattering capacity now in progress will, it is hoped, furnish significant information relevant to this question. Although a recogni-

¹ However, Jordan Lloyd claims that pure gelatin has a low "solubility" at even 100°C. *J. Biol. Chem.*, **16**, 530 (1921). Inasmuch as Schryver's highly purified gelatin apparently did not show this behaviour, the point needs re-examination. Knaggs, Schryver and Manning: *Biochem. J.*, **18**, 1079, 1085, 1095, 1102 (1924).

tion of parallelism may give small comfort as an "explanation" of gelatin behaviour, the conversion thereby of many unique cases to a class with a common feature is a distinct step in the direction of a more detailed and presumably fundamental description of the phenomena.

Summary

Quantitative studies of the light-scattering capacity (tyndall effect) have been made in order to obtain in a direct way insight into the strictly colloidal behaviour of aqueous gelatin systems. The maximum tyndall effect located very exactly the pH defining the isoelectric point. By this method, it was shown that the gelatins may possess isoelectric points between pH 4.8 and 5.5 (perhaps even to pH 8.). Blended gelatins containing components with different isoelectric points behaved like a single gelatin with an intermediate isoelectric point. It was pointed out that part of the difficulty in quantitatively interpreting gelatin behaviour in terms of the theory of ampholytes is due to the fact that all gelatins may be mixtures of an unknown number of unisolated chemical substances.

* A detailed study was made of the influence of acid, alkali, and temperature upon the tyndall effects of de-ashed gelatin. Above 30°C, the tyndall intensity indicated a high and approximately constant degree of dispersion at all pH's between 2.7 and 12.2. As the temperature fell below 30°C, an abrupt rise in tyndall intensity (i.e. a sharp fall in degree of dispersion) developed in the range of a few degrees over a fraction of a pH unit at the isoelectric point. A mere trace of acid or alkali sufficed to repress this change. A discussion was given of the significance of these facts for an understanding of the condition of gelatin in the sol state. It was suggested that the great effectiveness of acid or base in preventing the precipitation of de-ashed gelatin at ordinary temperatures is not to be interpreted in terms of the simple theory of ampholyte solubility. The analogies were discussed between the dispersion of isoelectric gelatin above 30°C and (1) solubility of a phase of constant composition, (2) conjugate solutions with a consolute temperature, and (3) colloidal systems with a critical peptization temperature. Gelatin and other protein systems may belong to case (2) or case (3), rather than to case (1).

NEW BOOKS

A Comprehensive Treatise on Inorganic and Theoretical Chemistry. By J. W. Mellor. Vol. VII. 25 × 17 cm; pp. x + 977. New York and London: Longmans, Green and Co., 1927. Price: \$20.00. And still the wonder grows that Mellor can turn out volume after volume in short order, since his only working time is in the evenings and the week-ends when he is not playing chess. The chapters in the seventh volume are entitled: titanium; zirconium; hafnium; thorium; germanium; tin; lead; inert gases.

"The pure element [titanium] has not been used to any great extent, but metal alloys have been used a good deal in ferrous and non-ferrous metallurgy. The ferro-titanium alloys are used as deoxidizers or denitrogenizers in iron and steel metallurgy, and they are also said to impart desirable qualities—*e.g.* toughness to the steel for certain purposes. According to Braune, the effect of nitrogen in steel is to increase slightly the toughness, and reduce the ductility. Hard steel with 0.030 to 0.035 per cent. of nitrogen is brittle, and soft steel with 0.05 to 0.06 per cent. loses its ductility. The presence of nitrogen is also said to favour the segregation of phosphorus and sulphur causing cold shortness. Titanium is said to remove the greater portion of the deleterious nitrogen from steel, at about 800°, by forming titanium nitride. For example, some remarkable results have been reported on the improvement of steel rails effected by the use of titanium. Thus the life of the rails in use is said to have been increased from 200 to 400 per cent. by the titanium treatment. Contradictory results have been reported on the effects produced by titanium in iron, because its action depends on the nature and proportions of the various constituents of the sample of iron investigated. Titanium alone does not readily alloy with iron and steel since it floats on the surface of the molten metal, and is difficult to dissolve; *master alloys* are therefore made—ferro-titanium, or ferro-carbotitanium—which when added to molten steel enable any desired proportion of titanium to be added to the metal. Silico-titanium or ferro-silico-titanium has been recommended when it is desirable to add both elements to steel. According to Rossi, the addition of one to two per cent. of titanium in molten copper by means of *cupro-titanium* as a master alloy eliminates oxide and absorbed gases and imparts a closer-grained structure than if titanium be absent, *mangano-titanium* is the master alloy which has been advertised as a deoxidizer in bronze manufacture. The effect of titanium on the magnetic properties of iron has been studied by Applegate—less than one per cent. of titanium in Swedish iron lessens the hysteresis losses; and increases the permeability whilst greater amounts increase the hysteresis losses.

"Titanium and some of its compounds have been employed in the manufacture of incandescent media for illumination—arc lamp electrodes, filaments for glow lamps, and gas mantles. The use of the metal or of the compounds of titanium—rutile, ilmenite, titanium oxide, or carbide, etc.—for this purpose depends on their high fusion and vaporization temperatures and their high radiation efficiency. Titanic oxide has been recommended in the manufacture of arc-lamp electrodes; and with rutile the results are said to be superior to those with carbon electrodes, particularly for street lighting. The positive electrode in the so-called *magnetite arc lamp* is made from a mixture of magnetite and chromite together with 15 to 25 per cent. of rutile or ilmenite, and it is operated on a direct, not alternating, current. It is claimed that this lamp gives a specially uniform distribution in a horizontal plane. It is also claimed that electrodes made wholly or partially of titanium carbide are comparatively free from the hissing of carbon electrodes, and that they give a steadier light and last longer. The use of titanium filaments for incandescent lamps has not been so successful on account of the rather greater efficiency of tungsten and tantalum filaments. Up to about two per cent. of titania in quartz-glass is said to improve the quality," p. 24.

"Titanous hydroxide is oxidized with the development of hydrogen: $2\text{Ti}(\text{OH})_3 = 2\text{TiO}_2 + 2\text{H}_2\text{O} + \text{H}_2$, and at the same time the colour passes through various shades of brown, red, violet, and blue to white. Manchot and Richter found that when titanium sesquioxide is

shaken with an aqueous solution of potassium hydroxide and oxygen, a considerably larger volume of oxygen is absorbed than corresponds with one equivalent of oxygen. The hydrogen peroxide primarily formed is reduced partially by the titanium sesquioxide, the remainder of the peroxide oxidizing the titanium dioxide to pertitanic acid on acidification or possibly even in the alkaline solution. If a thick milk of lime or baryta-water is used in place of the potassium hydroxide, the hydrogen dioxide formed is not reduced by the titanium sesquioxide or dioxide, and the whole of the oxygen absorbed is found in the form of hydrogen dioxide. If the solution of tervalent titanium in sulphuric acid is boiled with potassium hydroxide, it evolves a volume of hydrogen equal to that of the oxygen absorbed on shaking the alkaline solution with oxygen. The acid solution also evolves hydrogen when boiled, but only extremely slowly. When shaken with oxygen, a solution of tervalent titanium in sulphuric acid containing ferrous ammonium sulphate absorbs a still larger excess of the gas, and the solution contains ferric oxide, whereas an acid solution of ferrous ammonium sulphate alone does not absorb a measurable volume of oxygen," p. 29.

"The facts favour the assumption that normal ilmenite is ferrous metatitanate, FeTiO_3 , and that in the ferruginous varieties the metatitanate is isomorphously associated with ferric oxide; and that the ferrous metatitanate may also be associated in a somewhat similar manner with magnesium, calcium, and manganous metatitanates. Tammann found the temperature of formation from its constituent oxides is 700° . Ilmenite is fairly widely diffused in nature; it is a common constituent of igneous rocks, and appears to have been one of the earliest minerals to separate from the molten magma. It occurs associated with haematite in granites, syenites, diabases, gabbros, basalts, and other eruptive rocks. It also occurs associated with magnetite," p. 58.

"It is said that zirconium steel, i. e. steel with a small percentage of zirconium, is very hard and useful in making armour plates, armour-piercing projectiles, and bullet-shields. It is claimed that an armour plate one inch thick is equivalent to a plate of the best German steel three inches thick," p. 117.

"Mesothorium preparations are used in medicine as a substitute for radium preparations. Commercial mesothorium contains mesothorium-1, mesothorium-2, radiothorium, thorium-X, etc. Thorium minerals, monazite sand, or old gas mantles are used as raw material. This is digested with sulphuric acid. Part of the mesothorium is dissolved by the acid, but most remains undissolved. To prevent the dissolution of the mesothorium, a little barium carbonate or chloride is added. The liquid must be stirred so that the barium sulphate is formed throughout the whole mass of liquid; and enough barium salt should be added to precipitate all the mesothorium and radium in the solution. The mixture is treated with sodium carbonate to convert the sulphates to carbonates, or the sulphates are transformed into sulphides. The products are dissolved in hydrochloric acid, and the chlorides purified as in the case of radium salts," p. 187.

"Bunte and Luggin have shown that the trace of finely divided cerium oxide, on the surface of the thoria, is so active that under suitable conditions the mantle can be kept luminous in a stream of coal gas and air. A mica chimney is fixed over the mouth of a large Bunsen burner so as to form a prolongation of the tube. The mixture of gas and air is ignited at the mouth of the chimney, and the air supply is regulated so as to give a non-luminous flame. An ordinary Welsbach's mantle is then hooked by its loop on to a platinum wire, and is held on the burning mixture of gas and air at the mouth of the chimney, until it glows and emits light in the usual way. On lowering the mantle through the flame into the mica chimney below, it continues to incandesce in the cold current of air and gas," p. 216.

Wood, and Ives and co-workers give a hydraulic analogy for the behaviour of the burner and mantle. "Imagine the mantle to be represented by a vertical cylindrical tank into which water is flowing at a constant rate from a tap. Let the wall of the tank be perforated by holes of various sizes. The water which squirts out through these holes is the radiation, and the various sizes of holes represent various wave-lengths. If the smaller holes are more numerous at the top of the tank, then the higher the water rises the more will squirt out through the smaller holes, thus copying the behaviour of a material radiator, water

height being taken to represent *temperature*. If the tank contains many holes, the water will not rise very high, and, conversely, in one with only very few holes the water will rise higher, thus copying the behaviour of mantles of high and low emissive powers, in so far as their temperature characteristics are concerned. If the holes are all made small, only squirts of small size will be present, and the water will rise higher than if the holes of all sizes are present, thus copying the characteristics of a selective radiator like the mantle. In order for this tank to represent the behaviour of the mantle with respect to the amount of radiation, it is only necessary to imagine a vertical seam of the tank to have been left unsoldered, so that a bad leak is present, to represent the convection and conduction losses. The higher the water rises, as when the radiating holes are made in number, the more is lost through the leaky seam, and so the less is 'radiated' through the holes. Obviously, with a constant rate of supply the advantage of increased 'temperature' being more and more offset by the leakage," p. 219.

The chapter on germanium, pp. 254-275 is to a very large extent an account of the work of Dennis and his students at Cornell.

The early Britons smelted tin ore by a very simple process. "They placed the ore in a hole in the ground, and laid wood between and around it. They then set fire to the wood. The fire smelted the ore. The slag was run from the molten metal through a pipe or furrow into a second hole. Many of these slag-hearths are still found in Cornwall. The whole smelting process was as effective as it was simple; proof of this is found in the fact that the slag residues do not contain sufficient ore to warrant a second separation by more modern methods," p. 276.

"Tin, though one of the common metals, is the most sparsely distributed metal in common use. The known workable deposits of gold cover one and a half million square miles, while the known workable deposits of tin cover but one-twelfth of this area. There is scarcely a country where gold has not been or might not be profitably obtained; tin is confined to about a dozen districts in the world. The tin deposits of Cornwall so long famed in history are nearing exhaustion; the same might be said of the deposits in Bohemia, Tuscany, South Spain, and the Pyrenees. There are, indeed, comparatively few known workable deposits of tin in the World," p. 280.

Somebody should study the colors of stannous oxide which may be black, bluish-black, slate grey, red, green, or greenish-brown, depending on the mode of preparation, p. 387. The author is distinctly non-committal on the subject of alpha and beta stannic acids, p. 405. On p. 426 is the extraordinary statement that a very dilute solution of stannous chloride raises the boiling-point of methyl acetate about twice as much as it should. Stannic oxide gives a reversible jelly with aqueous sulphuric acid, p. 479.

"J. N. von Fuchs studied the reduction of manganic salts by stannous chloride. A. V. Harcourt showed that the greater the amount of water employed in the solution of a given amount of stannous chloride, the greater the amount of a standard solution of potassium permanganate required for the titration. If air-free water be employed this phenomenon is not observed. The same amount of permanganate is required, however much water be employed. It was hence inferred that the oxygen dissolved in the water as well as the permanganate oxidizes the stannous salt; but oxygen dissolved in water has no perceptible action on the stannous salt alone. Air can oxidize the stannous chloride only simultaneously with the permanganate. W. Ostwald called such reactions coupled reactions," p. 431.

"Lead emits a peculiar odor when rubbed between the fingers; the smell is probably not due to the metal, but to the organic substances—the fingers, for example, which come in contact with it. According to Percy, lead is feebly elastic or sonorous, and it furnishes a dull sound when struck with a hard substance; and the dullness of the sound, the 'leaden-ring,' is proportionate to the purity of the metal. R. A. F. de Réaumur reported that in 1726, Lemery discovered *par un pur hazard*, that if lead be cast into the shape of a segment of a sphere—i. e. mushroom-shaped—it has the novel and remarkable property of emitting sharp notes when struck with another piece of lead. The sonorous lead is rendered dull by hammering. Neumann also stated that lead cast into the form of a hollow spherical or

elliptical segment, is very sonorous. R. A. F. de Réaumur attributed the sonorous quality to the shape of the grains and to the way they touch one another. If the rounded grains are flattened by hammering, the elongated grains fill the interstitial spaces, and the particles are no longer free to vibrate, and the lead then emits a dull sound when struck. The velocity of sound in lead, according to Wertheim, is 1320 metres per second; and, according to Masson and Herz, in soft-lead at 15°-20°, 1227.4 metres per second," p. 524.

"Owing to the solvent action of the water supply on lead pipes in some towns in Lancashire and Yorkshire lead poisoning was prevalent for a considerable period before its real nature was recognized, and the cause discovered. Lead being a cumulative poison, may produce serious results if regularly taken in very minute quantities over long periods of time. The softest and purest water and peaty waters often act most readily on lead, so that lead has always been considered more or less dangerous metal in connection with the supply of portable water. These waters are treated with limestone to make them safe. The subject has therefore attracted a great deal of attention. The results of the various observations show that water of a moderate degree of temporary and permanent hardness, and containing but little dissolved nitrates and inappreciable quantities of ammonium salts, may be safely conveyed in lead pipes. Greenburg traced the lead in some cistern-water to the flashing on the roofs of buildings which collected the rain-water," p. 568.

"When plumbers strip the roofs of churches or other buildings, covered with lead which has lain undisturbed for many years, they usually find that side of the lead which is contiguous to the boards, covered with a white pellicle, as thick sometimes as a half-crown; this pellicle is corroded lead, and is as useful for painting, and other purposes, as the best white lead. The lead on the south side of any building is found to abound most with this white crust; that on the north side having very little, or none at all on it. It is believed, also, that lead which lies on deal boards is not so apt to be covered with this white incrustation, as that which lies upon oak: if there be any truth in this observation, it may, perhaps, be explained from hence, that oak contains a much stronger acid than deal, and this strong acid being distilled, as it were, by the heat of the sun in summer, attaches itself to the lead, and corrodes it: or this corrosion may be the effect of the sun and air, which, by their constant action, calcine or corrode the lead; and this calcined lead not being washed off by the rain, may, in the course of a great many years, form the crust here spoken of. Brame also observed the corrosion of lead in contact with oak, and Southerden said that the roofing of Axminster church laid on deal in 1833 was sound 85 years afterwards, but the portion laid on oak in 1909, was thickly encrusted with white lead after nine years. Dunsheath noted the corrosion of lead pipes in contact with oak. Cresse noted the perforation of sheet lead by a wood borer—Capricorn beetle, Goat beetle, or Sawyer worm," p. 573.

"Pliny also described how the Romans tested the harshness of wine by immersing in it a sheet of lead, and marking the corrosive action; they also sweetened some wine by boiling it in leaden vessels. Pliny does not seem to have thought the practice was attended by any danger. In the preparation of wine, if the fermentation process be carried too far, the liquor becomes charged with acid. The ancients probably knew that lead rendered harsh wine milder, and preserved it from acidity. The process was used with confidence because the toxic effects were not ascribed to the metal but to some other cause. The deleterious result of sweetening wine with lead compounds was mentioned by Citois in 1616, and Delamarc in 1696; and Zeller and Weismann said that the practice was invented in France. After the poisonous effects of this addition had been recognized, it required the severest of punishments—torture and death—before the use of litharge for this purpose could be stopped. Even in the eighteenth century, the improvement of wines by litharge was in some quarters taught as a method free from danger—*e. g.* by Graham—although J. Beckmann has cited a number of cases near the end of the seventeenth century, where those who treated the wines with lead compounds were very severely punished. The litharge or white-lead was singularly efficacious in renovating spoilt wine, but its effect on the consumer was disastrous. According to J. Beckmann, no adulteration of any article has ever been invented so pernicious to the health, and at the same time so much practised as that of wine

with preparations of lead; and as the inventor must have been acquainted with its destructive effects, he deserves, for making it known, severer execration than Berthold Schwartz, the supposed inventor of gunpowder.

"The wine occasions, according as it is used in a great or small quantity, and according to the constitution of the consumer, a speedy or a lingering death, violent colics, obstructions, and other maladies; so that one may justly doubt whether, at present, Mars, Venus or Saturn is most destructive to the human race," p. 588.

"Boltwood found the ratio of uranium to lead in primary minerals from the same locality to be so nearly constant as to suggest that lead may be the end-product of the degradation of uranium. The rate of radioactive change is so slow that direct proof of the degradation of uranium to lead cannot be expected. It has been calculated that a gram of uranium yields 1.25×10^{-10} grm. of radium-G per annum; and if the gram of uranium be constantly replenished to make up the loss, a gram. eq. of radium-G would require 8000 million years for its formation. A. Holmes has shown that with stable minerals of primary origin, where there is no geological or petrological evidence of the presence of lead as a primary product, and no evidence of the loss of any of the constituents by weathering, the age of the mineral can be estimated from the ratio Pb:U. The result shows that the age of some precambrian Norwegian minerals, in which this ratio is 0.103, approximates 1000 million years. The trustworthiness of the evidence was discussed by Kirsch," p. 602.

"Goebel found that the hardness of lead is increased by sodium from 4.1 when no sodium is present to 28.9 when 2 per cent is present; as the proportion of sodium is further increased to 5 per cent., the hardness drops to 18.4. Sperry, Thieme, and Mathewson also examined the hardness of these alloys. An alloy with 1.3 per cent. of sodium is called *noheat metal*, or *tempered lead*, and has been recommended as a bearing metal, and Patterson claimed that under these conditions some sodium hydroxide is formed, which, with the lubricating oil forms a kind of soap," p. 607.

"Henry found that when a bar of lead is bent in the form of a syphon, and placed with one end in the mercury, in due course the mercury will flow out at the other and lower end. With a bar made of non-hammered lead, the first drop of mercury appeared in 24 hrs., and when made of hammered lead, in 10 days," p. 618.
